Stannotriethyl-sulphide. Stannic sulphotriethide.

$$\mathrm{[\overset{\prime\prime\prime}{Sn}{}^2(C^2H^5)^6]''.(CO^3)''} \quad = \quad \mathrm{\overset{iv}{Sn}{}^2}\begin{cases}\mathrm{(C^2H^5)^6}\\ \mathrm{(CO^3)''}\end{cases}$$

Stannodiethyl-carbonate. Stannic carbonatodiethide.

Löwig has also described a number of stannethyls, which cannot be included in either of the preceding groups; they are represented by the following formulæ, using the old atomic weights, $C = 6$, $Sn = 59$:—

Acetostannethyl, $Sn^4(C^4H^3)^3$.
Ethstannethyl, $Sn^4(C^4H^5)^5$.
Radicle not named, $Sn^6(C^4H^5)^4$.
Methylene-stannethyl, $Sn^2(C^4H^5)^2$.
Ethylene-stannethyl, $Sn^4(C^4H^5)^4$.

---

Pharm. cv. 306; cxxiii. 365; Jahresb. 1858, p. 387; 1862, p. 398.

The last two are polymeric with stannodiethyl, *$Sn(C^4H^5)$*, according to Löwig. All these radicles are said to unite with 1 at. chlorine, bromine, iodine, &c.

Kekulé (Ann. Ch. Pharm. cxix. 190) supposes these anomalous stannethyl-compounds to be derived from the more simply-constituted radicles above mentioned, by substitution of iodine, chlorine, &c. for ethyl: thus, Löwig's iodide of acetostannethyl, $Sn^2(C^2H^5)^3I$, might be derived, in this manner, from a double molecule of stannodiethyl, $Sn^2(C^2H^5)^4$; and his iodide of ethstannethyl, $Sn^2(C^2H^5)^5I$, in like manner, from a double molecule of stannotriethyl, $Sn^2(C^2H^5)^6$.

Strecker has pointed out that Löwig's methylene- and ethylene-stannethyl are most probably identical with stannethyl, and that the compounds described by Löwig as iodide of methylene- and ethylene-stannethyl are oxyiodides of stannethyl, containing $Sn^2(C^2H^5)^4I^2O$ and $Sn^2(C^2H^5)^4I^2O^3$—compounds which Strecker has actually obtained by other processes (p. 827). In bodies whose molecular weights are as high as those of the stannethyl-compounds, the quantities of oxygen indicated by these formulæ would make but little difference in the percentage of the other elements.

It must further be observed, that the existence of these anomalous stannethyls is by no means well established. Löwig never succeeded in isolating them completely, or in preparing their compounds in a pure state; and Cahours was never able to obtain them at all, however much he might vary the proportions of the materials.

Preparation of Stannethyls.—1. Finely-divided tinfoil is introduced, together with three times its weight of ethylic iodide, into a strong glass tube, which is sealed and exposed to sunshine. A slow reaction then takes place, requiring several weeks' exposure to the summer sun for its completion; it may, however, be greatly accelerated by concentrating the rays with a parabolic reflector, and at the same time keeping the tube cool by immersion in water, or in solution of cupric sulphate; the reaction is then completed in a few days. The product solidifies to a crystalline mass, consisting mainly of stannic di-iododiethide, $Sn^{iv}(C^2H^5)^2I^2$, with small quantities of stannous iodide and stannic iodotriethide, $Sn^{iv}(C^2H^5)^3I$ (Frankland):

$$2C^2H^5I + Sn = Sn(C^2H^5)^2I^2.$$
$$3C^2H^5I + Sn^2 = Sn(C^2H^5)^3I + SnI^2.$$

2. A mixture of 1 pt. finely-cut tinfoil and 2½ to 3 pts. ethylic iodide, is enclosed in a sealed tube, and heated to 150° in an oil-bath for 20 or 30 hours. After *cooling*, the contents of the tube are found to consist partly of colourless crystals of stannic di-iododiethide (iodide of stannodiethyl), partly of yellowish crystals of stannic iodotriethide (iodide of stannotriethyl). On decanting the liquid from the crystals, and distilling, a small quantity of ethylic iodide passes over first; then, at 230°, the stannic iodotriethide; and at 245° the stannic di-iododiethide, the residue consisting of stannous iodide. (Cahours; Riche.)

3. Stannide of sodium, prepared by fusing 6 pts. of tin with 1 pt. of sodium, is finely pulverised, and mixed with quartz-sand in the proportion of 1 pt. of the alloy to 1—1½ pts. of sand; the mixture quickly introduced into a number of glass flasks of 3 or 4 ounces' capacity; and a quantity of ethylic iodide added, sufficient to form a thick paste: the flask is then briskly shaken, and a distillation-tube adapted to it. The action commences in a few minutes, and is completed the more quickly in proportion as the alloy is richer in sodium. The heat which it developes is sufficient to cause the excess of ethylic iodide to distil over, after which the flask, while yet warm, is closed airtight; after the mixture has cooled, the treatment with iodide of ethyl is renewed, and the same operation repeated till a sample of the contents of the flask no longer gives off hydrogen when thrown into water. The dry, dusty, yellowish, stinking mass, obtained in this manner from several flasks, is then transferred to a bottle filled with ether (from 4½ to 5 pounds to the contents of 16 flasks), left to stand for an hour or two, and frequently shaken; after which the dark-brown ethereal solution is poured into a bottle filled with carbonic anhydride, and left to stand for half an hour or an hour, whereupon, especially if there were any air in the bottle, a brown substance, which dries up in the air to a white inodorous mass, separates out. The ethereal solution is then transferred to a retort, mixed with about $\frac{1}{10}$ of its bulk of alcohol, and the ether is completely distilled off. There then remains a dark turpentine-like mass [consisting, according to Löwig, of the radicle $Sn^3(C^2H^5)^4$], and an alcoholic solution, which, when decanted and left at rest, deposits a large quantity of yellow oil, frequently separating, after some time, into two layers, the lower of which consists mainly of stannous ethide, $Sn''(C^2H^5)^2$, or stannodiethyl. The alcoholic liquid decanted from the yellow oil deposits, on addition of water, a nearly colourless oil, the first precipitated portion of which consists mainly of stannous

ethide, and the last of stannosostannic ethide or stannotriethyl; while the intermediate portions contain other radicles (p. 825), which, after conversion into iodides, may be separated by fractional crystallisation (Löwig). For Löwig's method of separating these supposed radicles, see *Gmelin's Handbook*, ix. 93.

Stannous Ethide, or **Stannodiethyl,** $Sn''(C^2H^5)^2$.—The method last described yields this radicle comparatively pure. The best method of obtaining it however is to immerse a strip of zinc-plate in a warm solution of stannodiethyl-chloride; it then collects at the bottom of the vessel, as a thick yellowish oil. (Frankland.)

Stannous ethide would probably be colourless when quite pure. It has a specific gravity of 1·558 at 15°, does not solidify at $-12°$, and cannot be distilled without decomposition. It has an extremely pungent odour, stronger than that of any of its compounds. It is insoluble in water, but soluble in *alcohol*, and still more soluble in *ether*.—It absorbs *oxygen* from the air, but does not fume or take fire; it reduces *nitrate of silver* immediately, with separation of black metallic silver; and unites directly with *chlorine*, *bromine*, and *iodine*.—With *hydrochloric*, *hydriodic*, *hydrobromic*, and *hydrofluoric acids*, it forms haloïd salts, with evolution of hydrogen. When heated to 150°, it boils, and is resolved into stannic ethide, $Sn(C^2H^5)^4$, which distils over, and metallic tin.

Compounds of Stannethyl.—These compounds, which, as already observed, may be regarded as belonging to the stannic type, are produced either by direct combination, or by double decomposition from the iodide.

BROMIDE, $Sn(C^2H^5)^2Br^2$.—Produced by treating an alcoholic solution of stannodiethyl with bromine, or by dissolving the oxide in hydrobromic acid; also, together with other compounds, by heating ethylic bromide with tin to 150°. It forms long white needles, having a faint camphorous odour, melts when gently heated, and distils without decomposition at 232°. Its vapour-density (taken at 295°) is 11·64; by calculation (2 vols.) = 11·74. It is soluble in water and alcohol, and especially in ether. (Löwig; Cahours.)

CHLORIDE, $Sn(C^2H^5)^2Cl^2$.—Obtained, in long colourless needles, by dissolving the oxide in dilute hydrochloric acid, and evaporating at a gentle heat. It melts at 60°, sublimes when slightly warmed, and boils without decomposition at 220°. Vapour-density = 8·71 and 8·62 at 268°—282° (Cahours); calc. = 8·62. It has a stronger odour than the bromide, is moderately soluble in boiling water, more easily in alcohol and in ether. (Löwig; Frankland; Cahours.)

When ammonia is added by drops to a boiling alcoholic solution of the chloride, till a permanent precipitate begins to form, this precipitate redissolved by addition of a little more of the stannodiethyl-chloride, and the liquid left to cool, white shining laminæ are deposited, consisting of stannodiethyl-oxychloride, $Sn^2(C^2H^5)^4OCl^2$. (Strecker.)

FLUORIDE, $Sn(C^2H^5)^2F^2$.—Obtained, in fine crystals, by evaporating the solution of stannethyl-oxide in hydrofluoric acid.

IODIDE, $Sn(C^2H^5)^2I^2$.—This compound is the direct product of the action of ethylic iodide upon tin, or upon sodium-stannide containing a small proportion of sodium, and is likewise easily produced by the action of iodine on stannodiethyl in ethereal solution. It forms colourless, inodorous, needle-shaped crystals, often several inches long, melts at 42°, sublimes at 160° in shining needles or laminæ, and boils, without decomposition, at 245°. It dissolves sparingly in cold, more easily in warm water, also in cold alcohol and ether. (Löwig; Frankland; Cahours.)

The warm aqueous solution of the iodide, mixed with a small quantity of ammonia, yields, on cooling, an oxyiodide, $Sn^4(C^2H^5)^8I^2O^3$, in hard prismatic crystals, slightly soluble in water, more soluble in alcohol or ether. The same crystals are obtained by boiling oxide of stannethyl with an alcoholic solution of the iodide. (Strecker.)

Iodocyanide, $Sn(C^2H^5)^2CyI$.—Produced by heating equivalent quantities of stannethyl-iodide and silver-cyanide with a small quantity of anhydrous alcohol, in sealed tubes immersed in a salt-bath. By evaporating the filtered solution, it is obtained as a crystalline powder.

OXIDE, $Sn(C^2H^5)^2O$.—Obtained, as a white powder, by evaporating an ethereal solution of stannodiethyl in contact with the air, or by precipitating a solution of a stannethyl-salt with ammonia. It is tasteless, inodorous, not volatile, takes fire when heated in contact with the air, burning with a bright flame, and giving off fumes of stannic oxide. It is insoluble in water and in ammonia, nearly insoluble in alcohol and ether, but dissolves easily in dilute acids and in the fixed alkalis. On distilling it with excess of aqueous potash, stannotriethylic hydrate passes over with the aqueous vapour, and stannate of potassium remains behind:

$$3Sn(C^2H^5)^2O + 2KHO = K^2SnO^3 + 2Sn(C^2H^5)^3(HO).$$

[illegible] stannethyl-oxide at a gentle heat, [illegible] oxychloride, which may be [illegible]

Stannosostannic Ethide, or **Stannotriethyl,** [illegible] $(C^2H^5)^3$]. *Sesquistan-nethyl.* [illegible]—The preparation [illegible] by Löwig's method has been already described (p. 826). [illegible] in excess to an alloy of 80 pts. [illegible] 20 pts. sodium in a retort, and after the spontaneous reaction is over, heats [illegible] with a small quantity of [illegible] in strong glass tubes for twenty hours to 120°. The contents of the tubes, when cold, are added to pure ether, and after twenty-four hours' digestion, the solution is filtered into vessels filled with carbonic anhydride, whereupon it deposits a white flocculent mass. The solution filtered therefrom is distilled to one-eighth of its original volume; and the residue is mixed with half its volume of ordinary alcohol, and further evaporated, till a clear yellowish oil settles down to the bottom of a viscid colourless liquid. This yellow oil, after washing with alcohol and heating to 170°–180°, constitutes pure stannotriethyl. This compound, according to Kulmiz, is a nearly colourless, heavy, slightly refractive oil, having a peculiar odour like that of rotten fruits. It unites directly with oxygen, chlorine, bromine, and iodine.

Compounds of Stannotriethyl.

These compounds may be regarded as formed by the union of 1 at. iodine, chlorine, &c. with 1 at. of the monatomic radicle $Sn'''(C^2H^5)^3$, or as stannic molecules, in which three of the four units of atomicity of the tin are neutralised by ethyl, and the fourth by a negative radicle (p. 825), the molecule being doubled for compounds containing diatomic negative radicles, such as S, O, SO^4, &c.; *e.g.*:

$$Sn'''(C^2H^5)^3.Cl \quad = \quad Sn^{iv}\left\{\begin{matrix}(C^2H^5)^3\\Cl\end{matrix}\right.$$

Stannotriethyl-chloride. **Stannic chloro-triethide.**

$$[Sn'''(C^2H^5)^3]^2.SO^4 \quad = \quad \overset{''''}{Sn}{}^2\left\{\begin{matrix}(C^2H^5)^6\\(SO^4)''\end{matrix}\right.$$

Stannotriethyl-sulphate. **Stannic sulphato-triethide.**

Their modes of formation are analogous to those of the stannethyl-compounds.

Bromide, $Sn(C^2H^5)^3Br$.—This salt is most easily obtained by treating the oxide with hydrobromic acid. It is a colourless, mobile, strongly refracting liquid, of specific gravity 1·630, and boiling at 223°. It has a very pungent odour, like that of mustard-oil, dissolves readily in ether and in alcohol, even when dilute, but very sparingly in water (Löwig; Cahours; Kulmiz). Vapour-density = 9·924 (Cahours); calc. = 9·60.

Chloride, $Sn(C^2H^5)^3Cl$.—Obtained by dissolving the oxide in hydrochloric acid, or (more readily) by adding that acid to an aqueous solution of the sulphite. It is a transparent, colourless, strongly refracting liquid, having a very powerful and suffocating odour. Specific gravity = 1·428 at 8° (Cahours), 1·320 (Kulmiz). Boils at 209°. Vapour-density (obs.) = 8·430 at 285°; calc. = 8·33. At 0° it solidifies in colourless prisms. According to Kulmiz, it forms, with *platinic chloride*, two crystalline compounds, containing $Sn^2(C^2H^5)^6Cl^2.PtCl^4$ and $Sn(C^2H^5)^3Cl.PtCl^4$, respectively. It also forms crystalline compounds with *auric* and *mercuric chloride*.

Cyanide, $Sn(C^2H^5)^3Cy$.—When stannotriethyl-iodide and silver-cyanide are gently heated together in a retort, this compound sublimes in snow-white crystals, which may be freed from a grey substance, often adhering to them, by solution in alcohol and spontaneous evaporation. It forms silky flexible prisms, which melt when gently heated, and sublime without decomposition. When quickly heated it suffers partial decomposition. It is nearly inodorous in the cold, but when heated, it emits an odour like that of prussic acid and the stannotriethyl-compounds together.

Hydrate, $\left.\begin{matrix}Sn'''(C^2H^5)^3\\H\end{matrix}\right\}O = Sn^{iv}(C^2H^5)^3(HO)$.—This compound is separated from solutions of stannotriethyl-salts by caustic potash, but generally remains dissolved. It may, however, be withdrawn from the solution by agitation with ether, and obtained in the crystalline form by leaving the ether to evaporate. When a solution of stannotriethyl-iodide is distilled with excess of potash, the hydrate passes over with the aqueous vapour, and solidifies in the crystalline form on cooling; and even when the alkaline solution is gently heated in a beaker-glass, the hydrate gradually sublimes, filling the entire space with slender crystals, which form a mass like cotton-wool. To obtain the hydrate from a mixture of the iodides of stannethyl and stannotriethyl—such as is ordinarily produced by the action of tin on ethylic iodide—the mixture is dissolved in alcohol; silver-oxide is added as long as silver-iodide is thereby produced; the solution containing the hydrate of stannotriethyl is filtered from the precipitate consisting of a mixture of stannethyl-oxide and silver-iodide; and the filtrate evaporated over oil of vitriol.

Stannotriethyl-hydrate forms colourless prismatic crystals, moderately soluble in alcohol, either anhydrous or hydrated, easily in ether. The solutions have a strongly alkaline reaction and caustic taste, precipitate most of the heavy metals from their solutions as oxides or hydrates, and absorb carbonic acid from the air. The hydrate neutralises acids completely, forming with most of them crystalline salts.

Iodide, $Sn(C^2H^5)^3I$.—This compound is produced in small quantity when tin is heated to 150° with ethylic iodide, more abundantly when an alloy of tin and sodium is used; also, together with ethylic iodide, by the action of iodine on stannic ethide:

$$Sn(C^2H^5)^4 + I^2 = C^2H^5I + Sn(C^2H^5)^3I.$$

The best mode of preparing it is to treat an alloy of 7 pts. tin and 1 pt. sodium with ethylic iodide, whereupon a brisk action takes place, accompanied by great rise of temperature. As soon as this action is over, the residue, mixed with ethylic iodide to a thin paste, is enclosed in sealed tubes, and heated, for eighteen or twenty hours, to 125°, or at most 130°. The tubes, when cold, are opened, the contents treated with ether, and the filtered solution evaporated, after addition of a little alcohol. On leaving the ether to evaporate, a yellowish oil separates, the quantity of which increases on addition of water; and on distilling this oil by itself, pure stannotriethyl-iodide passes over, between 230° and 235°. (Cahours.)

Stannotriethyl-iodide is a colourless, heavy, strongly refracting liquid, of specific gravity 1·833 at 22°, and boiling without decomposition between 235° and 238° (Cahours). It solidifies in a mixture of carbonic anhydride and ether. It has a pungent odour, attacking the nose and eyes like oil of mustard. It mixes in all proportions with absolute alcohol and with ether, dissolves sparingly in water, easily in hydrated alcohol. It dissolves iodine, with brown colour in the cold; but on heating the solution the free iodine disappears, and iodide of stannethyl is formed, together with iodide of ethyl.

Stannotriethyl-iodide absorbs *ammonia-gas*, forming the compound $Sn(C^2H^5)^3I.2NH^3$, which may be obtained in thin prisms, by adding a solution of the iodide to anhydrous alcohol saturated with ammonia-gas, warming the liquid for a few hours in the water-bath, and then leaving it to cool. It likewise forms crystalline compounds, of analogous composition, with *ethylamine*, *amylamine*, and *aniline*.

OXIDE, $Sn^2(C^2H^5)^6O$.—Obtained, by prolonged heating of the hydrate to a temperature near its boiling-point, as a transparent oil, which, when mixed with a small quantity of water, is reconverted into the crystalline hydrate. (Cahours.)

OXYGEN-SALTS.—These salts are obtained by dissolving the hydrate, oxide, or carbonate of stannotriethyl in the aqueous acids, or by decomposing the iodide with silver-salts. They are mostly crystalline, and dissolve readily in water, alcohol, and ether.

Acetate, $Sn(C^2H^5)^3(C^2H^3O^2)$.—Prepared by dissolving the oxide in acetic acid. Slightly soluble in water, easily in alcohol, whence it separates, by spontaneous evaporation, in tufts of white silky needles. It melts at a gentle heat, sublimes at a somewhat higher temperature in snowy flocks, and boils without decomposition at 230°. (Kulmiz; Cahours.)

Arsenate, $Sn(C^2H^5)^3(AsO^4)$.—White crystalline mass, soluble in alcohol, and crystallising therefrom in tufts of shining needles. (Kulmiz.)

Benzoate, $Sn(C^2H^5)^3(C^7H^5O^2)$.—Obtained by double decomposition from the iodide. Long, transparent, highly lustrous prisms, which melt at 80°, and sublime without decomposition at a higher temperature. Sparingly soluble in water, easily in alcohol, even when dilute. (Kulmiz.)

Butyrate, $Sn(C^2H^5)^3(C^4H^7O^2)$.—Thin shining needles, sublimable without decomposition, slightly soluble in cold water, moderately soluble in alcohol, especially when warm.

Carbonate, $Sn^2(C^2H^5)^6(CO^3)$.—The hydrate absorbs carbonic acid from the air during the evaporation of its alcoholic solution. The alcoholic solution of the sulphate, mixed with carbonate of ammonium or carbonate of sodium, deposits stannotriethyl-carbonate as a dazzling-white crystalline powder. (Kulmiz.)

Cyanate, $Sn(C^2H^5)^3(CNO)$.—Prepared by gradually adding dry cyanate of silver to an alcoholic solution of stannotriethyl-chloride, as long as the liquid is thereby coloured yellow. The filtrate left to evaporate yields the salt in tufts of thin prisms, having a silky lustre. It is moderately soluble in alcohol and in ether, is converted into carbonate by exposure to moist air, gives off carbonic anhydride when treated with strong acids, and ammonia when boiled with potash.

When ammonia-gas is passed into the alcoholic solution of this salt, and the liquid left to evaporate, there remains a substance which dissolves partially in alcohol; and this solution yields, by evaporation, long colourless prisms, regarded by Kulmiz and Cahours as stannotriethyl-carbamide, $\left.\begin{matrix}(CO)''\\H^3\\Sn(C^2H^5)^3\end{matrix}\right\}N^2$; but they are, perhaps, only a mixture of carbamide (urea) with a salt of stannotriethyl. They have not been analysed.

Formate, $Sn(C^2H^5)^3(CHO^2)$.—Thin prisms, having a silky lustre when dry, melting between 50° and 60°, and then subliming completely; very soluble in strong alcohol. (Cahours; Kulmiz.)

Nitrate, $Sn(C^2H^5)^3(NO^3)$.—Prepared by mixing an alcoholic solution of the hydrate with nitric acid, then adding ether and enough water to cause the liquid to separate into two layers, the upper of which contains the nitrate, and leaves it as a syrupy mass when evaporated. When cold it forms a transparent varnish, which dissolves easily in alcohol and ether, and burns away, when heated, with a faint light, but without detonation. (Löwig.)

Oxalate, $Sn^2(C^2H^5)^6(C^2O^4)''$.—A solution of oxalic acid in dilute alcohol takes up a large quantity of stannotriethyl-hydrate, and deposits the oxalate, on evaporation, in shining colourless prisms, sparingly soluble in cold, easily in warm water, alcohol, or ether. It is inodorous at ordinary temperatures, but decomposes when heated above 100°. (Cahours; Kulmiz.)

Phosphate, $\left.\begin{matrix}[Sn'''(C^2H^5)^3]' \\ H^2\end{matrix}\right\}(PO^4)''' = 2H^3PO^4.\overset{iv}{Sn^3}\left\{\begin{matrix}(C^2H^5)^9 \\ (PO^4)'''\end{matrix}\right.$.—Obtained by treating the carbonate with dilute phosphoric acid as long as effervescence is produced, as a white powder, which dissolves in very dilute alcohol, and separates, on evaporation, in tufts of transparent shining needles. It is moderately soluble in warm water, very soluble in dilute alcohol, slightly in ether. The solutions have an acid reaction. (Kulmiz.)

Sulphate, $Sn^2(C^2H^5)^6(SO^4)''$.—Separates from alcoholic solution in nearly transparent six-sided prisms with six-sided pyramidal summits (Kulmiz). It is more soluble in cold than in warm water, so that a solution saturated in the cold solidifies almost completely when heated (Buckton). It is easily soluble in alcohol. (Cahours.)

Tartrates.—The *neutral salt*, $Sn^2(C^2H^5)^6(C^4H^4O^6)''$, is obtained by treating the carbonate with excess of tartaric acid, dissolving the crystalline deposit in dilute alcohol, and leaving the solution to evaporate. It forms cubic crystals, which melt and decompose at a rather high temperature.—An *acid salt*, $Sn^2(C^2H^5)^6(C^4H^4O^6)''.C^4H^6O^6 + 2aq.$, is contained in the mother-liquor of the neutral salt; and on leaving this liquid to evaporate completely, washing the crystalline residue with a little water to remove excess of tartaric acid, then dissolving it in aqueous alcohol, and leaving the solution to evaporate, the acid tartrate separates in well-defined, shining, rhombic crystals, moderately soluble in water, easily in dilute alcohol. (Kulmiz.)

A few other oxysalts of stannotriethyl have been prepared, but not accurately investigated.—The *bromate* and *iodate*, formed by the action of bromine or iodine on an alcoholic solution of stannotriethyl-hydrate, separate in small shining crystals, which detonate slightly when heated (Löwig).—The *caproate*, *caprylate*, and *valerate* resemble the acetate and butyrate. (Cahours).

SULPHIDE, $Sn^2(C^2H^5)^6S$.—When an alcoholic solution of the hydrate is divided into two equal parts, one portion saturated with sulphydric acid, and the second portion added after the excess of sulphydric acid has been expelled by evaporation, the sulphide separates as a heavy oil, which may be dried over sulphuric acid. It is transparent, has an amber-yellow colour, strong refracting power, and a fetid odour. (Cahours; Kulmiz.)

SULPHYDRATE, $Sn(C^2H^5)^3(HS)$.—Obtained by saturating a solution of the hydrate in absolute alcohol with sulphydric acid gas, and evaporating, in colourless needle-shaped crystals having an odour of mercaptan. (Cahours.)

SULPHOCYANATE, $Sn(C^2H^5)^3(CNS)$.—Obtained by heating an alcoholic solution of the iodide with excess of silver-sulphocyanate in the water-bath, and evaporating, as a viscid, slightly amber-yellow mass, which gradually becomes crystalline. It melts when heated, and solidifies again in the crystalline state on cooling. It dissolves in alcohol and ether, and exhibits the general reactions of the two sulphocyanates. (Cahours.)

Stannic Ethide, or **Stannotetrethyl,** $Sn^{iv}(C^2H^5)^4$.—This compound is produced by the action of zinc-ethyl on iodide of stannodiethyl or iodide of stannotriethyl, the iodine being replaced by ethyl:

$$Sn(C^2H^5)^2I^2 + Zn''(C^2H^5)^2 = ZnI^2 + Sn(C^2H^5)^4.$$
$$2Sn(C^2H^5)^3I + Zn(C^2H^5)^2 = ZnI^2 + 2Sn(C^2H^5)^4.$$

It is also formed by the action of zinc-ethyl on stannic chloride (Buckton), and lastly in the distillation of stannous ethide, metallic tin being separated at the same time.

To prepare it, crystallised stannodiethyl-iodide (stannic di-iododiethide) is gradually added to an ethereal solution of zinc-ethyl, the crystals then dissolving with moderate rise of temperature, and a syrupy liquid being ultimately obtained. If this liquid —which should contain an excess of zinc-ethyl—be then distilled, the boiling-point quickly rises from 70° to 180°, and the greater part of the product passes over between 180° and 200°, while zinc-iodide and a small quantity of zinc-ethyl remain in the retort. The distillate contains a little zinc-ethyl, which must be decomposed by water, with addition of acetic acid, and the heavy oil which then settles down is separated from the supernatant watery liquid, dried over chloride of calcium, and rectified. (Frankland.)

Stannic ethide is a transparent colourless liquid, of specific gravity 1·87 at 23°. It remains liquid at −13°, and boils at 181°. Vapour-density, obs. = 8·021 (Frankland); calc. = 8·108. It has a faint ethereal odour, and a somewhat metallic but not unpleasant taste. It is inflammable, and burns with a dark-blue-edged flame, emitting white fumes of stannic oxide. In oxygen-gas it burns with a dazzling light.

Stannic ethide dissolves *iodine* with brown colour, which gradually disappears. If the addition of iodine be continued as long as the brown colour disappears without aid of heat, and the liquid be then distilled, ethylic iodide and afterwards stannotriethyl-iodide pass over (Buckton; Frankland). When the action of the iodine is assisted by a gentle heat, the decomposition goes further in the same direction, and a mixture of the iodides of ethyl and stannodiethyl is obtained (Cahours). Lastly, when stannic ethide is somewhat strongly heated with excess of iodine in a sealed tube, iodide of ethyl is produced, together with red iodide of tin. (Cahours.)

Stannic ethide reacts in a similar manner with *bromine*.

Stannic ethide is not decomposed by *water*, neither is it acted on by strong *hydrochloric acid* in the cold; but on heating the mixture over mercury to 80° or 90°, bubbles of hydric ethide are very slowly evolved, and stannotriethyl-chloride is produced (Frankland):

$$Sn(C^2H^5)^4 + HCl = C^2H^5.H + Sn(C^2H^5)^3Cl.$$

According to Cahours, the reaction takes place more quickly at 100°; and if it be longer continued, with a larger excess of hydrochloric acid, crystallised stannethyl-chloride is produced.

Stannic ethide mixes with *stannic chloride*, producing considerable rise of temperature, and forming chloride of stannotriethyl:

$$3Sn(C^2H^5)^4 + SnCl^4 = 4Sn(C^2H^5)^3Cl.$$

It also mixes with *chloride of stannethyl*, but without acting chemically upon it, at least at moderate temperatures. (Buckton.)

β. Methyl-compounds: Stannmethyls.[*]

These compounds are analogous in constitution to the stannethyls, which they also resemble, generally, in their properties and modes of formation. Their names and formulæ are as follows:

Stannous methide, or Stannodimethyl, $Sn''(CH^3)^2$.
Stannoso-stannous methide, or Stannotrimethyl, $2[(Sn''(CH^3)^3]$.
Stannic methide, or Stannotetramethyl, $Sn^{iv}(CH^3)^4$.

The first is a diatomic, the second a monatomic radicle; the third, in which the atomicity of the tin is fully satisfied, does not act as a radicle.

There are also tin-compounds of analogous constitution, containing both ethyl and methyl.

Stannous Methide, or **Stannodimethyl,** $Sn''(CH^3)^2$.—This compound is formed by heating methylic iodide with an alloy of 1 pt. sodium and 5 pts. tin, in sealed tubes to 130°. By exhausting the contents of the tubes with ether, and evaporating the solution in an atmosphere of carbonic anhydride, it is obtained, not quite pure, as a heavy oily liquid having a mouldy smell. It is insoluble in water, easily soluble in alcohol and ether, and is resolved by heat into stannic methide and metallic tin. The alcoholic solution forms, with nitrate of silver, a black precipitate of metallic silver.

The compounds of stannodimethyl may be regarded (like those of stannodiethyl) as stannic compounds, in which two out of the four units of atomicity of the tin are satisfied by methyl, and the other two by a negative radicle. They are formed either by direct combination, or from the iodide by double decomposition.

Bromide, $Sn(CH^3)^2Br^2$.—Obtained by treating the oxide with excess of hydrobromic acid, and separates from the concentrated liquid in crystals, which may be purified by recrystallisation from alcohol. They are colourless prisms, isomorphous with the corresponding chloride. The salt boils without decomposition at 208°—210°. It is moderately soluble in water, more easily in alcohol. (Cahours.)

Chloride, $Sn(CH^3)^2Cl^2$.—Separates, on evaporating a solution of the oxide in excess of hydrochloric acid, in fine prisms. It melts at 90°, and boils at 188°—190°. Vapour-density, obs. (at 265) = 7·731; calc. = 7·63. It dissolves in water, more easily in alcohol and in ether. (Cahours)

Iodide, $Sn(CH^3)^2I^2$.—Produced, like the corresponding ethyl-compound, by the action of tin on methylic iodide in sunshine (Frankland), or with aid of heat (Cahours and Riche). To prepare it, 2½ to 3 pts. methylic iodide are heated with 1 pt. of tinfoil to 150°—160°, in sealed tubes, for twelve to fifteen hours. The tubes, after cooling, contain a mixture of a brown liquid and sulphur-yellow crystals, and on subjecting this mixture to fractional distillation, methylic iodide passes over first after which the boiling-point gradually rises to 230°, and at last nothing but red iodide of tin is left. The distillate, on cooling, deposits yellow crystals of stannic di-iododimethide, and the mother-liquor decanted therefrom consists chiefly of stannic iodotrimethide; but if it be again rectified, the portion which last goes over will yield an additional quantity of stannic di-iododimethide. The crystals are pressed between paper, then dissolved in a mixture of alcohol and ether; and by leaving this solution to evaporate in a shallow vessel over oil of vitriol, in a dark place, crystals of considerable size may be obtained.

---

[*] Frankland, Ann. Ch. Pharm, lxxxv. 346; Jahresb. 1852, p. 572.—Cahours and Riche, Ann. Ch. Pharm. lxxxviii. 316; Jahresb. 1852, p. 577.—Cahours, Ann. Ch. Pharm. cxiv. 367; Jahresb. 1859, p. 426.

Stannic di-iododimethide, or iodide of stannodimethyl, forms oblique rhombic crystals, which become somewhat opalescent on exposure to the air. It melts at about 30° to a liquid resembling melted sulphur; and by piercing the crust which forms on cooling, and pouring out the still remaining liquid, it may be obtained in well-defined rhombic prisms. Specific gravity = 2·872 (at 22°). It boils regularly at 228°. It dissolves in water, especially when warm, and very easily in alcohol, wood-spirit, acetone, or ether. Ammonia separates white stannethyl-oxide, insoluble in excess of ammonia. (Cahours.)

Oxide, $Sn(CH^3)^2O$.—The precipitate, obtained in the manner just mentioned, forms, when washed with dilute alcohol and dried, a white, amorphous, tasteless powder, insoluble in water, alcohol, ether, and aqueous alkalis. When heated, it decomposes, giving off the odour of stannotrimethyl-oxide. When stannodimethyl-oxide is heated with excess of potash, stannotrimethyl-oxide volatilises with the aqueous vapour, and stannate of potassium remains behind:

$$3Sn(CH^3)^2O + 2KHO = K^2SnO^3 + Sn^2(CH^3)^6O + H^2O.$$

Oxygen-salts.—Most acids dissolve the oxide of stannodimethyl, forming crystallisable salts.—The *formate*, $Sn(CH^3)^2(CHO^2)^2$, crystallises in fine prisms, which, when heated, partly decompose, partly sublime unaltered.—The *butyrate* and *acetate* closely resemble the formate.—The *caprylate* and *valerate* crystallise easily, and are soluble in alcohol.—The *sulphate*, $Sn(CH^3)^2SO^4$, obtained by decomposing the iodide with silver-sulphate, or by dissolving the oxide in a slight excess of dilute sulphuric acid, and evaporating over oil of vitriol, crystallises in colourless prisms, often of considerable size. It is soluble in water, especially when warm, nearly insoluble in alcohol even at the boiling heat. It decomposes completely when heated, emitting a pungent odour. (Cahours.)

Stannosostannic Methide, or **Stannotrimethyl,** $Sn'''(CH^3)^3$.—This radicle is not known in the free state. Its compounds, which may be regarded as stannic molecules containing 3 at. methyl and 1 at. of a negative radicle, are produced by several reactions:—

1. The iodide is formed, together with stannodimethyl-iodide (p. 832) and stannic iodide, by the action of tin on methylic iodide at 130°—160°:

$$6(CH^3)I + Sn^3 = SnI^4 + 2Sn(CH^3)^3I.$$

2. The iodide is formed, together with methylic iodide, by the action of iodine on stannic methide at ordinary temperatures:

$$Sn(CH^3)^4 + I^2 = CH^3I + Sn(CH^3)^3I.$$

3. The oxide is formed, together with stannic oxide, by boiling stannic di-iododimethide with excess of potash:

$$3Sn(CH^3)^2I^2 + 3K^2O = Sn^2(CH^3)^6O + SnO^2 + 6KI.$$

The *iodide*, $Sn(CH^3)^3I$, is best prepared by heating tin with methylic iodide to 150°—160° in sealed tubes, and separating the stannodimethyl-iodide formed at the same time, by repeated rectification. The portion which passes over between 180° and 200°, if rectified till it no longer becomes turbid on cooling, and no longer deposits crystals of stannic iodide, yields pure stannotrimethylic iodide. (Cahours.)

This iodide is a thin colourless liquid, of specific gravity 2·153 at 18°, and boiling at 188°—190°. Vapour-density (at 260°) = 10·325; calc. = 10·049. It has a pungent odour like that of mustard-oil, but not so strong as that of the corresponding ethyl-compound. It remains liquid at the temperature of a mixture of ice and salt, but solidifies immediately at that of a mixture of ether and solid carbonic anhydride. (Cahours.)

Oxide and *Hydrate.*—When the iodide is mixed with excess of potash ley, the hydrate remains dissolved, but passes over on distilling the liquid, and collects in the receiver, together with water, as an oil which solidifies to a crystalline mass; and by pressing this mass between paper, and again rectifying, it may be obtained in colourless transparent prisms. It volatilises without decomposition, but, when heated for some time to a temperature near its boiling-point, it is resolved into water and anhydrous stannotrimethyl-oxide. It is sparingly soluble in water, more soluble in alcohol; the solutions are alkaline, and neutralise the strongest acids.

Oxygen-salts.—These salts are nearly all soluble, crystallise easily, are isomorphous with the corresponding stannotriethyl-salts, and volatilise without decomposition, emitting a pungent odour.

Formate, $Sn(CH^3)^3(CHO^2)$.—Somewhat concentrated formic acid, added to a saturated solution of the oxide, produces a precipitate which redissolves on heating the liquid, more easily on addition of alcohol. The solution, if left to evaporate, yields fine prismatic crystals, which melt at a gentle heat, and sublime without decomposition at a higher temperature. They dissolve easily in alcohol and ether.—The *acetate*, $Sn(CH^3)^3(C^2H^3O^2)$, is prepared like the formate, which it resembles in external characters. It volatilises without decomposition, dissolves easily in alcohol, less easily in water.—The *sulphate*, $\overset{iv}{Sn}{}^2(CH^3)^6(SO^4)''$, crystallises in small, colourless, shining prisms, easily soluble in water and in alcohol. (Cahours.)

Stannic Methide, or Stannotetramethyl, $Sn(CH^3)^4$. *Stannodimethyl. Stannobimethyl.*—This compound is produced by the action of zinc-methyl on stannic di-iododimethide, or stannic iodotrimethide, thus:

$$Sn(CH^3)^2I^2 + Zn(CH^3)^2 = ZnI^2 + Sn(CH^3)^4.$$
$$2Sn(CH^3)^3I + Zn(CH^3)^2 = ZnI^2 + 2Sn(CH^3)^4.$$

Also, together with metallic tin, by the distillation of stannous methide: $2Sn(CH^3)^2 = Sn(CH^3)^4 + Sn$.

It is a liquid having an ethereal odour, and boiling at 140°—145°. Iodine converts it into methylic iodide and stannic iodotrimethide.

By the action of zinc-ethyl on stannic iodomethides, and of zinc-methyl on stannic iodo-ethides, stannic compounds are produced, containing both ethyl and methyl, viz.:

$$2Sn(CH^3)^3I + Zn(C^2H^5)^2 = ZnI^2 + 2Sn(C^2H^5)(CH^3)^3.$$
$$Sn(C^2H^5)^2I^2 + Zn(CH^3)^2 = ZnI^2 + Sn(C^2H^5)^2(CH^3)^2.$$
$$2Sn(C^2H^5)^3I + Zn(CH^3)^2 = ZnI^2 + 2Sn(C^2H^5)^3(CH^3).$$

Stannic Ethotrimethide, $Sn(C^2H^5)(CH^3)^3$, is prepared by gradually adding stannic iodotrimethide to zinc-ethyl in a vessel cooled by immersion in cold water, the zinc-ethyl being kept in excess. On distilling the product, and mixing the distillate with water containing a little acetic acid, stannic ethotrimethide separates as a heavy oil, which is to be washed, dried with chloride of calcium, and rectified. It is a colourless liquid, of specific gravity 1·243, and boiling between 123° and 128°. Vapour-density, obs. (at 200°) = 6·715; calc. = 6·65. It has an ethereal, somewhat pungent odour. With iodine it forms ethylic iodide and stannic iodotrimethide (Cahours):

$$Sn(C^2H^5)(CH^3)^3 + I^2 = C^2H^5I + Sn(CH^3)^3I.$$

Stannic Diethodimethide, $Sn(C^2H^5)^2(CH^3)^2$, is obtained by gradually adding stannic di-iododiethide to an ethereal solution of zinc-methyl, keeping the latter in excess, and proceeding as in the preparation of the last-described compound.

It is a clear colourless liquid, having a faint ethereal odour, and metallic taste. Specific gravity = 1·232 at 19°. It remains fluid at −13°, and boils between 144° and 146°. Vapour-density, obs. (at 199°) = 6·838; calc. = 7·138. It is easily set on fire, and is decomposed by chlorine, bromine, and iodine, which take from it 1 at. methyl.

Iodine dissolves in the liquid with carmine-red colour, which disappears slowly in the cold, more quickly on application of heat. On adding an excess of iodine, removing this excess after a while by means of metallic mercury, and distilling, methylic iodide passes over first; the boiling-point then quickly rises to 207°, at which temperature very little passes over; and there remains a straw-coloured, somewhat oily, intolerably pungent liquid, having a specific gravity of 2·033 at 15°, and the composition of stannosostannic iododiethide, $Sn'''(C^2H^5)^2I$. It remains liquid at −13°, and begins to boil at 208°; but the temperature quickly rises, and at 230°, an abundant separation of iodide of tin takes places. The liquid is, perhaps, a mixture of stannic di-iododiethide, $Sn(C^2H^5)^2I^2$, and stannous ethide, $Sn(C^2H^5)^2$. (Frankland.)

Stannic diethodimethide, treated with aqueous hydrochloric acid, gives off a mixture of ethylic and methylic hydrides (more than four times as much of the former as of the latter), and is converted into a crystalline salt, probably a mixture of stannic dichlorodiethide and stannic dichlorodimethide. (Frankland.)

Stannic Triethomethide, $Sn(C^2H^5)^3(CH^3)$, is produced by the action of stannic iodotriethide on zinc-methyl, and separates, on treating the distillate with acidulated water, as a heavy oil, which may be purified as above. It is a colourless liquid, having an ethereal odour, boiling at 162°—163°, and is converted by iodine into methylic iodide and stannic iodotriethide. (**Cahours.**)

γ. AMYL-COMPOUNDS: STANNAMYLS.

These compounds, investigated, under Löwig's direction, by A. **Grimm** (Ann. Ch. Pharm. xcii. 383; Jahresb. 1854, p. 543), are produced by the action of amylic iodide on an alloy of 1 pt. sodium and 6 pts. tin, the process being conducted as in Löwig's method of preparing the stannethyls (p. 826). The distilled product contains the compounds $Sn''(C^5H^{11})^2$, $[Sn'''(C^5H^{11})^3]^2$, and $Sn^{iv}(C^5H^{11})^4$, homologous with the stannethyls, and, according to **Grimm**, also a compound containing $Sn^2(C^5H^{11})^2$.

The stannamyls are unctuous masses, insoluble in water, easily soluble in ether, and more soluble in alcohol in proportion as they contain less tin. They have not a very pungent odour, and do not fume in the air. They reduce silver-solution, and are oxidised with great violence by nitric acid. Bromine also acts violently on them; and iodine, in alcoholic solution, attacks them with evolution of heat. Their ethereal solutions oxidise when evaporated in contact with the air. The oxides have an alkaline reaction, dissolve in acids, and are separated from the solution by ammonia. Neither the radicles nor their compounds can be volatilised without decomposition. According to **Grimm**, all the stannamyls above mentioned act as radicles, uniting with oxygen, chlorine, iodine, &c. With respect to stannic amylide, $Sn(C^2H^5)^4$, however, this statement is very improbable, inasmuch as the corresponding ethyl- and methyl-compounds react as saturated molecules, not as radicles. Altogether, the investigation of the stannamyls must be regarded as imperfect; they have not, indeed, been separated, one from the other, with sufficient accuracy to give any value to the special description their properties, or of those of their compounds.

TIROLITE. Syn. with TYROLITE.

TITANATES.
TITANIC ACID. } See TITANIUM (p. 844).

TITANIFEROUS IRON. See TITANATES OF IRON (p. 846).

TITANITE. Syn. with SPHENE (p. 398). **Hautefeuille** (Compt. rend. lix. 698; Jahresb. 1864, p. 216) has obtained crystals having the form and composition of sphene, by fusing in a platinum crucible a mixture of 3 pts. silica and 4 pts. titanic oxide covered with chloride of calcium. If a small quantity of manganous chloride be added to the mixture, crystals of **greenovite** are obtained. If the mixture, in the fused state, be exposed to an atmosphere of aqueous vapour and carbonic acid, or (better) of air saturated with aqueous vapour and hydrochloric acid, crystals of **perowskite**, $Ca''Ti''O^3$, are obtained. (See TITANATES, p. 845.)

TITANIUM. *Symbol*, Ti; *Atomic weight*, 50.—A metallic element discovered, in 1789, by **Gregor**, in the menaccanite (titaniferous ironsand) of Cornwall, and thence named, by **Kirwan**, *Menachin*. **Klaproth**, in 1795, discovered a new metal in rutile, which he called *Titanium*; but on subsequent investigation, in 1797, he found that this metal was identical with the menachin of Gregor. The name titanium has, however, been universally adopted. The preparation and properties of titanium and its compounds have been studied chiefly by **Berzelius**, **Wöhler**, and **H. Rose**.

Titanium is one of the rarer metals, and is never found in the metallic state. The most important titanium minerals are rutile, brookite, and anatase, which consist of titanic oxide, TiO^2, and the several varieties of titaniferous iron, consisting of ferrous titanate, sometimes alone, but more generally mixed with ferric or ferroso-ferric oxide. Titanium likewise occurs native, as titanate of calcium, in perowskite; as silico-titanate of calcium in sphene or titanite; and as titanate of cerium, yttrium, &c., together with tantalates and niobates, in æschynite, euxenite, polymignite, polycrase, and pyrochlore. Small quantities of titanium are found also in many iron-ores, and it has been detected by **Mazade** (Compt. rend. xxxiv. 952) in the mineral water of Negrac (Dép. d'Arêche) in France.

When titaniferous iron-ores are smelted in the blast-furnace, small cubic crystals of a bright copper-colour are found on the slag which adheres to the lower part of the furnace. These crystals were long supposed to be metallic titanium, but **Wöhler** (Ann. Ch. Pharm. lxxiii. 34) has shown that they also contain carbon and nitrogen,—being, in fact, a compound of cyanide of titanium with nitride of titanium, $TiCy^2.3N^2Ti^3$.

Pure titanium is obtained by heating the double fluoride of potassium and titanium with potassium in a covered crucible. The metal is then set free, with vivid incandescence, and the fluoride of potassium may be removed by washing with water. Titanium thus obtained is a dark-green, heavy, amorphous powder, which does not exhibit any shade of copper-colour, even after pressure; under the microscope it appears as a cemented mass, having the colour and lustre of iron. Metallic titanium is also obtained by mixing titanic oxide with one-sixth of its weight of charcoal, and exposing it to the strongest heat of an air-furnace. It was thus obtained, in the form of a copper-coloured or gold-coloured powder, by Vauquelin, Lampadius, and others; but possibly the charcoal which they used may have contained nitrogen, and that element may have united with the reduced metal.

Pure titanium (prepared from the double fluoride) burns with great splendour when heated in the air, and, if sprinkled into a flame, is consumed, with brilliant scintillations, at a considerable distance above the point of the flame. When heated to redness in oxygen-gas, it burns with a splendour resembling a discharge of electricity. In chlorine-gas it exhibits similar phenomena, requiring also the aid of heat to set it on fire. Mixed with red lead and heated, it burns with such violence that the mass is thrown out of the vessel with loud detonation. Titanium does not decompose water at ordinary temperatures, but on heating the water to the boiling-point, hydrogen begins to escape. Warm hydrochloric acid dissolves titanium, with brisk evolution of hydrogen. Ammonia added to the solution throws down a black oxide; and on heating the liquid, hydrogen is evolved; and the precipitate first turns blue, and is afterwards converted into white titanic acid.

Titanium, in its most important compounds, is tetratomic, titanic oxide being TiO^2, and the corresponding chloride, $TiCl^4$, analogous to the oxide and chloride of silicon; it also forms a sesquioxide, Ti^2O^3, and a corresponding trichloride, $TiCl^3$.

TITANIUM, ALLOYS OF. These alloys have not been much examined. A compound of titanium and aluminium, Al^6Ti, is obtained by exposing 10 pts. titanic oxide, 30 pts. cryolite, and 30 pts. of a mixture of equal weights of potassium- and sodium-chlorides, for an hour, to the heat of melting silver, and dissolving out the excess of aluminium from the resulting regulus with hydrochloric acid. It forms pinchbeck-brown, microscopic, quadratic laminæ, which, when heated in hydrochloric acid gas, are resolved into chloride of aluminium and chloride of titanium. (Wöhler and Michel, Ann. Ch. Pharm. cxiii. 248; cxv. 102; Jahresb. 1860, p. 129.)

Respecting the alloys of titanium and iron, see IRON, iii. 370.

TITANIUM, BROMIDE OF. Only one bromide of titanium is known, namely the tetrabromide, $TiBr^4$, which is obtained by passing bromine-vapour over an ignited mixture of charcoal and titanic oxide. It then distils over as a red liquid, which solidifies in the receiver to a crystalline mass. When freed from excess of bromine by redistillation with mercury, it forms an amber-yellow mass, having a beautiful crystalline structure and a density of 2·6, melting at 39°, and boiling at 230°. It quickly absorbs moisture, and in contact with water, is resolved into hydrobromic acid and titanic acid.

TITANIUM, CHLORIDES OF. Titanium forms two chlorides, $TiCl^3$ and $TiCl^4$.

The *Trichloride*, or *Titanous Chloride*, discovered by Ebelmen (Ann. Ch. Phys. [3], xx. 385), is produced by the action of hydrogen on the tetrachloride. To prepare it, pure and dry hydrogen-gas is passed into titanic chloride contained in a tubulated retort, by means of a delivery-tube dipping into the liquid. To the neck of the retort is adapted a tube of glass or porcelain (if of glass, it should be wrapped in copper-foil), which passes horizontally through a furnace, projecting considerably beyond it, and terminating in a tubulated receiver to collect the titanic chloride which passes undecomposed through the tube. As soon as the apparatus is completely filled with hydrogen, the tube is heated to redness, and the retort containing the titanic chloride is gently warmed. Titanous chloride is then produced, and condenses in the part of the tube which projects beyond the furnace, the process being finished as soon as all the titanic chloride is driven out of the retort. The projecting part of the tube is then to be gently warmed, while hydrogen is continually passed through it in order to drive all the undecomposed titanic chloride into the receiver, and the titanous chloride is then left to cool in the current of hydrogen.

Titanous chloride forms dark-violet scales, having a strong lustre. When heated in a porcelain dish in contact with the air, it gives off vapours of titanic chloride, and leaves titanic oxide. It deliquesces in the air at ordinary temperatures, and is gradually decomposed in the same manner. Titanous chloride dissolves in water, forming a violet-red solution, which gradually loses its colour, and deposits titanic acid. From the aqueous solution, alkalis and alkaline carbonates throw down dark-brown titanous hydrate; the same precipitate is formed by sulphide of ammonium; sulphuric acid produces no reaction. The solution of titanous chloride is an extremely powerful deoxidising agent, reducing the noble metals from their solutions, converting cupric and ferric salts into cuprous and ferrous salts respectively, and separating sulphur from ulphurous acid when heated therewith. (Ebelmen.)

A violet-red solution of titanous chloride is also produced by boiling or digesting a solution of titanic acid in hydrochloric acid with finely-divided silver. (v. Kobell.)

Tetrachloride of Titanium, or *Titanic Chloride*.—This compound is produced by heating titanium, or nitride of titanium, in chlorine-gas. It is prepared in the same manner as chloride of silicon—namely, by mixing finely-divided titanic oxide to a paste with oil and charcoal, heating the mixture in a covered crucible, and igniting the charred mass in a porcelain tube through which a current of chlorine is passed. The titanic chloride is collected in a cooled receiver, freed from excess of chlorine by agitation with copper or mercury, and then rectified. If native rutile has been used in the preparation, ferric chloride is likewise produced; but the titanic chloride is easily separated from it by decantation and redistillation.

Pure titanic chloride is a colourless, transparent, heavy liquid, having an acid pungent odour, and emitting white fumes on exposure to the air. It has a specific gravity of 1·7609 at 0°, does not solidify at $-25°$, and boils at 135°. Vapour-density, obs. $= 6·836$ (Dumas); calc. (2 vols.) $= 6·653$. When exposed to the air, it absorbs moisture, and gradually solidifies to hydrated titanic chloride, which dissolves in a larger quantity of water. According to Merz (Bull. Soc. Chim. 1867, i. 401) the product thus formed is an oxychloride, $TiCl^4.3TiO^2.16H^2O$ (nearly), which gives off part of its chlorine, as hydrochloric acid, when placed over quicklime, more when heated to 100°, and nearly all the remainder at 180°. On mixing the anhydrous chloride with water, combination takes place, attended with so great a rise of temperature that the mass is scattered about. To obtain a clear aqueous solution of the chloride, it must be added to cold water by small quantities, care being taken that the liquid does not become heated. On heating, and evaporating the aqueous solution, hydrochloric acid is evolved, and titanic acid is precipitated. Titanic chloride is not decomposed by potassium at its boiling-point; but when its vapour is passed over heated potassium or sodium, the titanium is reduced, with incandescence, and evolution of heat sufficient to melt the glass at the point where the reaction takes place. (H. Rose.)

Titanic chloride forms a number of compounds, analogous to those of stannic chloride:—

α. With Ammonia, $TiCl^4.4NH^3 = (N^4H^{12}Ti^{iv})Cl^4$ (Wöhler); $TiCl^4.6NH^3$ (Persoz).—Dry ammonia-gas, passed over titanic chloride, is rapidly absorbed, with great evolution of heat. The saturated compound is a brown-red powder (Rose), pale-yellow (Persoz), which quickly decomposes in contact with the air. When heated in ammonia-gas, it is converted into nitride of titanium (p. 841). By ignition in hydrogen, it yields a yellow compound. When heated by itself, in a glass tube, it first gives off ammonia, then chloride of ammonium and hydrochloric acid, leaves a residue of metallic titanium, and yields a yellowish-white sublimate, consisting of a double chloride of ammonium and titanium, containing $3NH^4Cl.TiCl^4$, or $6NH^4Cl.TiCl^4$, according to the mode of preparation. This double salt is soluble in water. (H. Rose.)

β. With Chloride of Cyanogen, $2TiCl^4.Cy^2Cl^2$.—Already described under CYANOGEN (ii. 280).

γ. With Hydrocyanic Acid, $TiCl^4.HCy$. (See ii. 220.)

δ. With Phosphoretted Hydrogen.—Titanic chloride absorbs dry phosphoretted hydrogen-gas, forming, when saturated, a brown solid body, which fumes in contact with the air. It is decomposed by water, hydrochloric acid, potash, ammonia, and their carbonates, giving off phosphoretted hydrogen with effervescence. Gaseous ammonia likewise expels the phosphoretted hydrogen at ordinary temperatures, converting the brown compound, for the most part, into the ammonio-tetrachloride above described. The brown compound, when heated in a close vessel, gives off a little hydrochloric acid and phosphoretted hydrogen, and yields a yellow sublimate, containing $3TiCl^4.2H^3P.2HCl$, which likewise gives off phosphoretted hydrogen when treated with water, acids, or alkalis. (H. Rose, Pogg. Ann. xlii. 527.)

ε. With Tetrachloride of Sulphur. (See p. 536 of this volume.)

ζ. With Chloride of Ammonium (see above).

TITANIUM, CYANIDES OF. See CYANIDES (ii. 273).

TITANIUM, DETECTION AND ESTIMATION OF. 1. *Blowpipe Reactions*.—The oxides of titanium are not reduced to the metallic state when heated on charcoal before the blowpipe, a character by which titanium is distinguished from tin.

Titanic oxide mixed with borax, or (better) with phosphorus-salt, forms in the outer blowpipe-flame a colourless glass; but in the inner flame, a glass which is yellow while hot, but assumes a violet colour on cooling. The same character is exhibited by those salts of titanic acid whose bases do not themselves impart any colour to the bead. If the titanic oxide contains iron, the colour of the bead is brown-red or blood-red, instead of violet. Many titanates yield the violet colour only with phosphorus-salt, not with borax. The colour is produced more readily by heating the substance on charcoal than on platinum-wire. According to Riley (Chem. Soc. Qu. J. xii. 13; Jahresb. 1859, p. 678), the delicacy of the reaction is much increased by melting a little metallic zinc in the phosphorus-salt bead, a distinct coloration being then produced, as the zinc is burnt away, even with very minute quantities of titanium.

2. *Reactions in Solution.*—Titanic acid and the neutral titanates are insoluble in water, but dissolve in acids, especially in hydrochloric and sulphuric acids. From these solutions the titanic acid is precipitated by boiling, imperfectly from the hydrochloric, completely from the sulphuric solution.—*Caustic alkalis* and *alkaline carbonates* likewise throw down from these solutions a white gelatinous precipitate of titanic acid. In the hydrochloric solution, containing as little free acid as possible, *infusion of galls* produces an orange-coloured precipitate.—*Ferrocyanide of potassium* forms, in the same solution, a dark-brown precipitate.—Metallic *tin*, immersed in a solution of titanic acid in hydrochloric acid, eliminates hydrogen, assumes a violet-blue colour, and, if the solution is not too dilute, throws down a dark-violet precipitate (protoxide of titanium?), which gradually turns white by oxidation. The violet-blue solution, when diluted with water, assumes a rose-colour, which often remains unaltered for several days. This reaction serves for the detection of very small quantities of titanium. (v. Kobell.)

Titanous oxide dissolves in acids, forming violet solutions, in which *alkalis* and *alkaline carbonates* form a dark-brown precipitate of titanous hydrate, gradually changing, with evolution of hydrogen, into titanic acid.—*Carbonate of calcium* precipitates titanous oxide completely from its solutions.—*Sulphydric acid* produces no alteration; *sulphide of ammonium* throws down brown titanous hydrate. The solution of titanous salts act as powerful reducing agents, precipitating *gold*, *mercury*, and *silver* from their solutions in the metallic state. Titanous chloride throws down white cuprous chloride from the solution of a *cupric salt*, and reduces *ferric* to *ferrous salts*. (Ebelmen).

3. *Estimation and Separation.*—Titanium is always estimated in the form of titanic oxide, TiO^2. This compound is best precipitated from its solutions in acids by ammonia, which throws it down in the form of a very bulky hydrate (titanic acid) resembling hydrate of alumina. A great excess of ammonia must be avoided, as it would redissolve a small portion of the titanic acid. The precipitate, after ignition, contains 60 per cent. of titanium.

If the titanic acid, after precipitation by ammonia, is to be redissolved in acids, which is sometimes necessary in order to separate it from other metals, great care must be taken in the precipitation to avoid all rise of temperature; and the precipitate must be washed with cold water, because heat has the effect of rendering titanic acid more or less insoluble in acids (p. 844).

Titanic acid may also, in some cases, be separated from its acid solutions by boiling; from the solution in sulphuric acid, complete precipitation is effected by this method; but when hydrochloric acid is the solvent, a small portion of titanic acid always remains in solution after boiling.

Titanic oxide (rutile, &c.) and its insoluble compounds are most easily rendered soluble by fusion with acid sulphate of potassium. The best mode of proceeding is to fuse in a platinum-crucible a quantity of the acid sulphate equal to about six times the weight of the titanate, add the mineral in extremely fine powder to this cooled mass, and fuse again till the whole flows quietly, and the powder is completely dissolved. The fused mass is then dissolved in a large quantity of cold water, and the solution precipitated by boiling.

Sesquioxide of titanium is precipitated from its solutions by ammonia, and the precipitate, after standing from 24 to 36 hours, is converted, with evolution of hydrogen, into titanic acid, in which form it may be estimated.

From the alkalis and alkaline earths, titanic acid may be separated by *ammonia*, the solution, in the latter case, being carefully excluded from the air. Baryta and strontia may also be separated by sulphuric acid.

Titanic acid is separated from magnesia by boiling, if the two are dissolved in sulphuric acid; and by precipitation with *carbonate of barium*, when hydrochloric acid is the solvent.

The separation from alumina, glucina, yttria, and thorina is also effected by boiling the sulphuric acid solution.

From zirconia, titanic acid may be separated by mixing the nearly neutralised solution with *hyposulphite of sodium*, and boiling till no more sulphurous anhydride is given off. The titanic acid is then completely precipitated, while the zirconia resolution.

From cerium and the allied metals, titanium is separated by precipitating the former with sulphate of potassium.

From the metals which are precipitated as sulphides by sulphide of ammonium—viz., manganese, iron, cobalt, nickel, uranium, and zinc—titanium is separated by mixing the acid solution with tartaric acid and excess of ammonia (which then forms no precipitate), and adding *sulphide of ammonium*, which precipitates everything but the titanium. The filtered solution is then evaporated to dryness, and the residue ignited in a platinum-crucible to expel ammoniacal salts, and burn away the carbon of the tartaric acid. As this carbonaceous matter is very difficult to burn, the ignition should either be performed in a muffle-furnace, or a stream of oxygen should be very gently directed into the crucible. The residue consists of titanic oxide, which may then be weighed.

The separation of titanium from iron may also be effected by precipitation with *hyposulphite of sodium*, the process being conducted exactly in the same manner as in separating aluminium from iron (i. 155).—For Riley's method of estimating titanium in pig-iron, see IRON, CARBURETTED (iii. 375).

From molybdenum, tungsten, and vanadium, titanium may be separated by means of sulphide of ammonium, which dissolves those metals as sulphides, and precipitates the titanium as titanic acid.

From bismuth, cadmium, copper, lead, tin, &c., titanium is easily separated by sulphydric acid.

Titanium may also be separated from tin, by fusing a mixture of stannic and titanic oxides with *sulphur* and *carbonate of sodium*. On treating the fused mass with water, the whole of the tin dissolves as sulphostannate of sodium, while the titanic acid remains undissolved, together with a small quantity of sodic titanate, which may be decomposed by ignition with sal-ammoniac; the chloride of sodium thereby formed may be dissolved out by water, leaving pure titanic acid.

From silicon.—When silicates containing small quantities of titanic acid are decomposed, in the usual way, by treatment with acids, or by fusion with an alkaline carbonate, the silica separated by evaporation, &c., and the alumina, ferrous oxide, and manganous oxide precipitated by ammonia, the greater part of the titanic acid will be found in this precipitate, while the smaller portion remains with the silica. The latter is treated with hydrofluoric and sulphuric acids, and the residue, consisting of titanic oxide, is mixed with the previously ignited precipitate of alumina, &c. This mixture is then fused with twice its weight of acid sulphate of potassium till the excess of sulphuric acid is for the most part volatilised, and the cooled mass is dissolved in water; whereby, if the operation has been well conducted, and the silica completely removed, a perfectly clear solution will be obtained. This solution is largely diluted, and sulphydric acid gas is passed through it, till the whole of the ferric oxide is reduced to ferrous oxide; and the solution, without previous filtration, is boiled for half an hour, while a stream of carbonic anhydride is continually passed through it (to prevent oxidation of the ferrous salt). The titanic acid is thereby completely precipitated, while all the other substances remain in solution. (Scheerer, Ann. Ch. Pharm. cxii. 178.)

In treating titaniferous silica with hydrofluoric acid to expel the silicon, the addition of sulphuric acid is indispensable, as otherwise a portion of the titanium will also be volatilised as fluoride. (Riley, Chem. Soc. Qu. J. xv. 311; Jahresb. 1862, p. 590.)

From tantalum and niobium, titanium is separated by fusing the mineral with acid sulphate of potassium, and treating the fused mass with cold water, which dissolves only the acid sulphate of titanium (iv. 51; v. 664).

Volumetric Estimation.—A method of estimating titanium volumetrically is founded on the reducibility of titanic oxide to titanous oxide by zinc in an acid solution, and the oxidability of the latter by permanganate of potassium. The titanic acid is dissolved in hydrochloric acid (if sulphuric acid is present, the titanic acid must first be precipitated by ammonia and then redissolved), the solution warmed with metallic zinc (in a flask provided with a vertical tube, so as to exclude the air as much as possible), till the colour of the liquid no longer increases in depth; and the solution, after dilution with de-aërated water, is mixed with permanganate of potassium, till the rose-red colour of the latter becomes manifest. Each atom of iron corresponding to the permanganate gives 1 at. titanium. (F. Pisani, Compt. rend. lix. 208; Jahresb. 1864, p. 705.)

A mixture of titanic oxide and zirconia is first rendered soluble by fusion with acid sulphate of potassium; the titanic acid is then determined as above, and the zirconia by difference.

Ferric oxide is reduced by zinc before titanic acid, and ferrous oxide is oxidised by the permanganate after it. To estimate iron and titanium together, the permanganate red, instead of violet. Many titanates yield the violet colour only with phosphorus-salt, not with borax. The colour is produced more readily by heating the substance on charcoal than on platinum-wire. According to **Riley** (Chem. Soc. Qu. J. xii. 13; Jahresb. 1859, p. 678), the delicacy of the reaction is much increased by melting a little metallic zinc in the phosphorus-salt bead, a distinct coloration being then produced, as the zinc is burnt away, even with very minute quantities of titanium.

2. *Reactions in Solution.*—Titanic acid and the neutral titanates are insoluble in water, but dissolve in acids, especially in hydrochloric and sulphuric acids. From these solutions the titanic acid is precipitated by boiling, imperfectly from the hydrochloric, completely from the sulphuric solution.—*Caustic alkalis* and *alkaline carbonates* likewise throw down from these solutions a white gelatinous precipitate of titanic acid. In the hydrochloric solution, containing as little free acid as possible, *infusion of galls* produces an orange-coloured precipitate.—*Ferrocyanide of potassium* forms, in the same solution, a dark-brown precipitate.—Metallic *tin*, immersed in a solution of titanic acid in hydrochloric acid, eliminates hydrogen, assumes a violet-blue colour, and, if the solution is not too dilute, throws down a dark-violet precipitate (protoxide of titanium?), which gradually turns white by oxidation. The violet-blue solution, when diluted with water, assumes a rose-colour, which often remains unaltered for several days. This reaction serves for the detection of very small quantities of titanium. (v. **Kobell.**)

Titanous oxide dissolves in acids, forming violet solutions, in which *alkalis* and *alkaline carbonates* form a dark-brown precipitate of titanous hydrate, gradually changing, with evolution of hydrogen, into titanic acid.—*Carbonate of calcium* precipitates titanous oxide completely from its solutions.—*Sulphydric acid* produces no alteration; *sulphide of ammonium* throws down brown titanous hydrate. The solution of titanous salts act as powerful reducing agents, precipitating *gold*, *mercury*, and *silver* from their solutions in the metallic state. Titanous chloride throws down white cuprous chloride from the solution of a *cupric salt*, and reduces *ferric* to *ferrous salts*. (**Ebelmen**).

3. *Estimation and Separation.*—Titanium is always estimated in the form of titanic oxide, TiO^2. This compound is best precipitated from its solutions in acids by ammonia, which throws it down in the form of a very bulky hydrate (titanic acid) resembling hydrate of alumina. A great excess of ammonia must be avoided, as it would redissolve a small portion of the titanic acid. The precipitate, after ignition, contains 60 per cent. of titanium.

If the titanic acid, after precipitation by ammonia, is to be redissolved in acids, which is sometimes necessary in order to separate it from other metals, great care must be taken in the precipitation to avoid all rise of temperature; and the precipitate must be washed with cold water, because heat has the effect of rendering titanic acid more or less insoluble in acids (p. 844).

Titanic acid may also, in some cases, be separated from its acid solutions by boiling; from the solution in sulphuric acid, complete precipitation is effected by this method; but when hydrochloric acid is the solvent, a small portion of titanic acid always remains in solution after boiling.

Titanic oxide (rutile, &c.) and its insoluble compounds are most easily rendered soluble by fusion with acid sulphate of potassium. The best mode of proceeding is to fuse in a platinum-crucible a quantity of the acid sulphate equal to about six times the weight of the titanate, add the mineral in extremely fine powder to this cooled mass, and fuse again till the whole flows quietly, and the powder is completely dissolved. The fused mass is then dissolved in a large quantity of cold water, and the solution precipitated by boiling.

Sesquioxide of titanium is precipitated from its solutions by ammonia, and the precipitate, after standing from 24 to 36 hours, is converted, with evolution of hydrogen, into titanic acid, in which form it may be estimated.

From the **alkalis** and **alkaline earths**, titanic acid may be separated by *ammonia*, the solution, in the latter case, being carefully excluded from the air. Baryta and strontia may also be separated by sulphuric acid.

Titanic acid is separated from **magnesia** by boiling, if the two are dissolved in sulphuric acid; and by precipitation with *carbonate of barium*, when hydrochloric acid is the solvent.

The separation from **alumina**, **glucina**, **yttria**, and **thorina** is also effected by boiling the sulphuric acid solution.

From **zirconia**, titanic acid may be separated by mixing the nearly neutralised solution with *hyposulphite of sodium*, and boiling till no more sulphurous anhydride is given off. The titanic acid is then completely precipitated, while the zirconia remains in solution.

From cerium and the allied metals, titanium is separated by precipitating the former with sulphate of potassium.

From the metals which are precipitated as sulphides by sulphide of ammonium—viz., manganese, iron, cobalt, nickel, uranium, and zinc—titanium is separated by mixing the acid solution with tartaric acid and excess of ammonia (which then forms no precipitate), and adding *sulphide of ammonium*, which precipitates everything but the titanium. The filtered solution is then evaporated to dryness, and the residue ignited in a platinum-crucible to expel ammoniacal salts, and burn away the carbon of the tartaric acid. As this carbonaceous matter is very difficult to burn, the ignition should either be performed in a muffle-furnace, or a stream of oxygen should be very gently directed into the crucible. The residue consists of titanic oxide, which may then be weighed.

The separation of titanium from iron may also be effected by precipitation with *hyposulphite of sodium*, the process being conducted exactly in the same manner as in separating aluminium from iron (i. 155).—For Riley's method of estimating titanium in pig-iron, see Iron, Carburetted (iii. 375).

From molybdenum, tungsten, and vanadium, titanium may be separated by means of sulphide of ammonium, which dissolves those metals as sulphides, and precipitates the titanium as titanic acid.

From bismuth, cadmium, copper, lead, tin, &c., titanium is easily separated by sulphydric acid.

Titanium may also be separated from tin, by fusing a mixture of stannic and titanic oxides with *sulphur* and *carbonate of sodium*. On treating the fused mass with water, the whole of the tin dissolves as sulphostannate of sodium, while the titanic acid remains undissolved, together with a small quantity of sodic titanate, which may be decomposed by ignition with sal-ammoniac; the chloride of sodium thereby formed may be dissolved out by water, leaving pure titanic acid.

From silicon.—When silicates containing small quantities of titanic acid are decomposed, in the usual way, by treatment with acids, or by fusion with an alkaline carbonate, the silica separated by evaporation, &c., and the alumina, ferrous oxide, and manganous oxide precipitated by ammonia, the greater part of the titanic acid will be found in this precipitate, while the smaller portion remains with the silica. The latter is treated with hydrofluoric and sulphuric acids, and the residue, consisting of titanic oxide, is mixed with the previously ignited precipitate of alumina, &c. This mixture is then fused with twice its weight of acid sulphate of potassium till the excess of sulphuric acid is for the most part volatilised, and the cooled mass is dissolved in water; whereby, if the operation has been well conducted, and the silica completely removed, a perfectly clear solution will be obtained. This solution is largely diluted, and sulphydric acid gas is passed through it, till the whole of the ferric oxide is reduced to ferrous oxide; and the solution, without previous filtration, is boiled for half an hour, while a stream of carbonic anhydride is continually passed through it (to prevent oxidation of the ferrous salt). The titanic acid is thereby completely precipitated, while all the other substances remain in solution. (Scheerer, Ann. Ch. Pharm. cxii. 178.)

In treating titaniferous silica with hydrofluoric acid to expel the silicon, the addition of sulphuric acid is indispensable, as otherwise a portion of the titanium will also be volatilised as fluoride. (Riley, Chem. Soc. Qu. J. xv. 311; Jahresb. 1862, p. 590.)

From tantalum and niobium, titanium is separated by fusing the mineral with acid sulphate of potassium, and treating the fused mass with cold water, which dissolves only the acid sulphate of titanium (iv. 51; v. 664).

Volumetric Estimation.—A method of estimating titanium volumetrically is founded on the reducibility of titanic oxide to titanous oxide by zinc in an acid solution, and the oxidability of the latter by permanganate of potassium. The titanic acid is dissolved in hydrochloric acid (if sulphuric acid is present, the titanic acid must first be precipitated by ammonia and then redissolved), the solution warmed with metallic zinc (in a flask provided with a vertical tube, so as to exclude the air as much as possible), till the colour of the liquid no longer increases in depth; and the solution, after dilution with de-aërated water, is mixed with permanganate of potassium, till the rose-red colour of the latter becomes manifest. Each atom of iron corresponding to the permanganate gives 1 at. titanium. (F. Pisani, Compt. rend. lix. 208; Jahresb. 1864, p. 705.)

A mixture of titanic oxide and zirconia is first rendered soluble by fusion with acid sulphate of potassium; the titanic acid is then determined as above, and the zirconia by difference.

Ferric oxide is reduced by zinc before titanic acid, and ferrous oxide is oxidised by the permanganate after it. To estimate iron and titanium together, the permanganate is added till the violet colour disappears, and a drop of the liquid begins to be coloured, by sulphocyanate of potassium. The quantity of permanganate required for this purpose gives the titanic acid, and by further addition the iron may be determined. Or the ferric oxide may be reduced by sulphurous or sulphydric acid (neither of which acts upon titanic acid), and volumetrically determined by itself. In a mixture of titanic acid, zirconia, and ferric oxide, the first and third are determined as just described, and the zirconia by difference. (Pisani.)

4. *Atomic Weight of Titanium.*—H. Rose, in 1829 (Pogg. Ann. xv. 145), determined the atomic weight of this metal by decomposing a weighed quantity of titanic chloride, $TiCl^4$, with water, precipitating the titanic acid with ammonia, and estimating the amount of chlorine in the filtrate with nitrate of silver. In four experiments, 100 pts. titanic chloride yielded, as a mean, 301·7 pts. silver-chloride; whence (for $Ag = 108$, and $Cl = 35·5$) the atomic weight of titanium was found to be $= 48·26$.

An essentially similar method was followed by Pierre in 1867 (Ann. Ch. Phys. [3], xx. 257), who, however, made use of a titrated silver-solution, instead of weighing the chloride of silver. In five experiments, each made with from 700 to 800 milligrammes of titanic chloride, he found that 100 pts. of that compound required to precipitate the chlorine contained in them from 224·58 to 225·53 pts. silver. Hence Ti falls between 49·50 and 50·38, and, as a mean result of the five experiments, $Ti = 50·10$. The whole number, 50, is now generally adopted.

TITANIUM, FLUORIDE OF. *Titanous Fluoride*, TiF^3, is obtained (though impure) as a violet powder, by igniting potassio-titanic fluoride (*infra*) in a stream of hydrogen-gas, and treating the resulting mass with hot water. (R. Weber, Pogg. Ann. cxx. 287; Jahresb. 1863, p. 211.)

Titanic Fluoride, TiF^4, is obtained by distilling a mixture of fluor-spar and titanic oxide with fuming sulphuric acid in a platinum apparatus; it then passes over as a fuming colourless liquid (Underdorben). By dissolving titanic acid in hydrofluoric acid, and evaporating, a syrupy liquid is obtained, which deposits crystals of titanic fluoride. These crystals are resolved by water into soluble hydrotitanic fluoride, and insoluble titanic oxyfluoride.

Hydrotitanic Fluoride, $H^2TiF^6 = 2HF.TiF^4$, is produced, as just stated, in the decomposition of titanic fluoride by water; also by dissolving titanic oxide in aqueous hydrofluoric acid (Berzelius). It is an acid, and, when neutralised with bases, yields double salts of titanic fluoride, represented by the general formula, $2MF.TiF^4$.

Ammonio-titanic Fluoride, $2NH^4F.TiF^4$, is produced by adding ammonia to aqueous hydrotitanic fluoride, till the precipitated titanic acid no longer redissolves. On evaporating the liquid, it separates in shining scales, which, when heated in a platinum apparatus, yield, much below a red heat, a sublimate of ammonium-fluoride, leaving a residue probably consisting of $NH^4F.TiF^4$. (Berzelius.)

Calcio-titanic Fluoride forms prismatic crystals, which dissolve without decomposition in acidulated water, but are decomposed by pure water, with separation of a white powder.—*Cupro-titanic fluoride*, obtained by mixing the solutions of the component fluorides, crystallises in long, pale, blue-green needles, soluble without decomposition in acidulated water.—The *ferric salt*, $2FeF^3.TiF^4$, is produced by mixing the solutions of the component salts. The yellow solution leaves, on spontaneous evaporation, a yellow syrup, and when gently heated, a pale-yellow crystalline mass, soluble in water without decomposition.—The *magnesium-salt*, prepared in like manner, separates by spontaneous evaporation in long needles, which have a bitter taste, are decomposed by pure water, but dissolves without decomposition in acidulated water.—The *lead-salt*, prepared in like manner, forms small colourless crystals, which have a sweet and afterwards an astringent taste, and dissolve readily in water without decomposition (Berzelius).—The *nickel-salt*, $NiF^2.TiF^4.6H^2O$, is produced by dissolving titanic acid and nickel-oxide in hydrofluoric acid, and separates in green, easily soluble crystals. (Weber.)

The *potassium-salt*, $2KF.TiF^4$, prepared like the ammonium-salt, crystallises in scales, which, when dry, are milk-white, and have a silky lustre (Berzelius).—Wöhler prepares it by fusing very finely-pounded rutile in a platinum-crucible with twice its weight of potassic carbonate, and dissolving the fused and pulverised mass in a platinum-dish, in the requisite quantity of dilute hydrofluoric acid. The double fluoride then partly crystallises out, and on heating the liquid to the boiling-point, adding water if necessary till the salt is redissolved, and filtering hot, the greater part separates in shining scales, so that the entire liquid solidifies to a pulp. The salt is to be washed on a filter with cold water, pressed between filter-paper, and crystallised from boiling water. It forms nacreous scales when dry, and melts without decomposition at a white heat.

The *sodium-salt* forms indistinctly crystalline crusts, more soluble than the potassium-salt. (Berzelius.)

TITANIUM, IODIDE OF. TiI^4. (R. Weber, Pogg. Ann. lxx. 287.—Hautefeuille, Bull. Soc. Chem. 1867, i. 201.)—Produced: 1. By passing iodine-vapour over ignited titanium (Weber).—2. By passing dry hydriodic acid·gas into titanic chloride gradually heated to its boiling-point, and maintained at that temperature till the transformation is complete: the small quantity of free iodine which gives the product a violet tinge may be removed by three or four distillations in a stream of hydrogen (Hautefeuille).—3. By passing the vapour of titanic chloride, mixed with hydrogen and iodine-vapour, through a tube heated to dull redness. The iodide, which is not very volatile, then condenses in the cold part of the tube, mixed, however, with a large quantity of free iodine, which renders it more difficult to purify than that obtained by the second method. (Hautefeuille.)

Titanic iodide forms a brittle mass, having a reddish-brown colour and metallic lustre. It melts to a brown liquid at 150°, remains in a state of surfusion till cooled somewhat below 100°, and crystallises on further cooling, in bulky octahedrons, which change, in a few days, to tufts of silky prismatic crystals. It has a sensible vapour-tension at ordinary temperatures, and fumes strongly in the air. It boils at a little above 360°, and distils without decomposition. Vapour-density, obs. (at 440°) = 18·054; calc. = 19·334. The lower density found by observation indicates an increased coefficient of expansion at high temperatures, perhaps arising from dissociation. The superheated vapour burns, in contact with the air, with a very bright flame, yielding iodic and titanic oxides.

Titanic iodide dissolves rapidly in water, but with less rise of temperature than the chloride. The aqueous solution, when exposed to the air, turns brown, and yields titanic acid.

TITANIUM, NITRIDES OF. By heating the ammonio-chloride of titanium, $4NH^3.TiCl^4$, by itself (H. Rose), or better in a stream of ammonia-gas (Liebig), a copper-coloured substance is obtained, which was originally supposed to be metallic titanium, but which Wöhler has shown to consist of nitride of titanium, Ti^3N^4, or more probably $Ti^6N^8 = 3TiN^2.Ti^3N^2$; it contains 28 per cent. of nitrogen. This compound is redder than the cubic crystals of the blast-furnaces, which have a tinge of yellow. Another nitride of titanium, TiN^2, is produced when titanic oxide is strongly heated in a stream of ammoniacal gas. Its powder is dark-violet, with a tinge of copper-colour; in small pieces it exhibits a violet copper-colour and metallic lustre. A third nitride, Ti^5N^6, or more probably $2TiN^2.Ti^3N^2$, is formed when Rose's titanium is subjected to the action of a stream of hydrogen at a strong red heat. It has a brassy or almost golden-yellow colour and metallic lustre. It is also obtained (mixed, however, with carbon) when titanic oxide is heated to redness in a stream of cyanogen-gas or hydrocyanic acid vapour; no cyanide of titanium is formed in this reaction. All these three nitrides of titanium sustain, without decomposition, a temperature at least equal to that of melting silver. Mixed in the state of powder with the oxides of copper, lead, or mercury, and heated, they emit a lively sparkling flame, and reduce the oxides to the metallic state. When fused with hydrate of potassium, they give off ammonia-gas. (Wöhler, Ann. Ch. Pharm. lxxiii. 34; Jahresb. 1849, p. 267.)

Wöhler and Deville (Ann. Ch. Pharm. ciii. 230; cv. 108; Jahresb. 1857, p. 174), by heating fluoride of titanium and potassium or sodium in an atmosphere of nitrogen, and boiling out the cooled mass with hydrochloric acid, obtained a nitride of titanium in the form of a dark-brown powder, composed of brass-yellow laminæ and prisms. When titanic chloride is passed through a strongly-ignited glass tube, in the fore part of which lumps of sal-ammoniac are placed, so that this salt may be volatilised with the titanic chloride, hydrochloric acid and nitride of titanium are immediately formed (the nitrogen being derived from the air), the latter coating the inside of the tube with a copper-coloured deposit. Nitride of titanium is also formed by heating a mixture of fluoride of titanium and potassium, chloride of sodium, and chloride of potassium, with aluminium; or by heating a mixture of titanic chloride and hydrogen-gas with aluminium, in presence of nitrogen.

TITANIUM, NITROCYANIDE OF. $TiCy^2.3Ti^3N^2$.—This is the copper-coloured compound already spoken of as occurring in iron-smelting furnaces, and formerly mistaken for metallic titanium. (See CYANIDES, ii. 273.)

TITANIUM, OXIDES OF. Two oxides of titanium are known with certainty, viz. Ti^2O^3, and TiO^2; the existence of a lower oxide, TiO, is likewise probable.

Protoxide of Titanium, TiO?—This oxide appears to be formed when titanic oxide is exposed, in a charcoal-lined crucible, to the highest heat of an air-furnace. Where the oxide is in contact with the charcoal, a thin coating of metallic titanium is formed; but within it is changed to a black mass, which is insoluble in all acids, is not otherwise affected by them, and is oxidised with difficulty when heated in contact with the air, or fused with nitre. The same oxide appears to be formed, in the wet way, as a dark-purple powder, when a fragment of zinc or iron is introduced into a solution of titanic acid in hydrochloric acid; but it alters very quickly by absorption of oxygen, so that there is considerable difficulty in studying its properties; the composition assigned to it is therefore hypothetical. The blue powder is, perhaps, a compound of titanium-protoxide with oxide of zinc or iron.

Sesquioxide of Titanium, or **Titanous Oxide,** Ti^2O^3.—This oxide is obtained, by passing dry hydrogen-gas over ignited titanic oxide, as a black powder, which, when heated in the air to a very high temperature, oxidises to titanic oxide. It is not attacked by nitric or hydrochloric acid; sulphuric acid dissolves it, forming a violet solution (Ebelmen).—A hydrate of titanous oxide, or titanous hydrate, is formed (according to Fuchs) by digesting a solution of titanic acid in hydrochloric acid at 40° or 50° with metallic copper, and pouring the resulting violet-blue solution into aqueous ammonia: it then falls down as a dark-brown precipitate, while cuprous chloride remains in solution. Instead of copper, silver reduced by zinc may be used in the preparation (v. Kobell). The hydrate is likewise formed (according to Ebelmen) when a solution of titanous chloride is precipitated by alkalis. The dark-brown precipitate thereby formed gradually turns black, blue, and finally white, while hydrogen is evolved. The blue colour is, perhaps, due to the formation of a titanous titanate.

Titanous oxide dissolves in *acids*, forming violet solutions; but the sulphate is the only titanous oxysalt that has been obtained in the solid state (see SULPHATES, p. 616). Titanous chloride has been already described. The solutions of titanous salts are powerful reducing agents, and yield a brown precipitate of titanous hydrate with alkalis (p. 838).

Dioxide of Titanium, Titanic Oxide or **Anhydride,** TiO^2. *Anhydrous Titanic acid.*—This oxide occurs native in three different forms: viz., as rutile and anatase, which are dimetric, and as brookite, which is trimetric. Rutile, which is the most common form of titanic oxide, occurs in acuminated dimetric prisms, isomorphous with tinstone, and exhibiting the combination P . ∞P . P∞ . ∞P∞ (*fig.* 322, ii. 160), also without P∞. For P, the length of the principal axis is 0·6442. Angle P : P = 123° 8′ in the terminal, and 84° 40′ in the lateral edges. Twin crystals occur, formed in the same manner as those of stannic oxide (p. 815). The crystals cleave distinctly parallel to ∞P and ∞P∞. Hardness = 6 to 6·5. Specific gravity = 4·18 to 4·25. Lustre, metallic adamantine. Colour reddish-brown, passing into red; sometimes yellowish, also black. Streak pale-brown. Subtransparent to opaque. Fracture subconchoïdal, uneven. Brittle.

Rutile occurs in granite, gneiss, mica-slate, and syenitic rocks; sometimes in granular limestone; generally in imbedded crystals. It is found in Brazil, at Arendal in Norway, on the Saualp in Carinthia, in the Urals, in the Tyrol, on the St. Gothard, at Yrieix in France, at Krumhennersdorff near Freiberg, in Castile, at Ohlapian in Transylvania, at Cairngorm in Scotland, at Craig Cailleach near Killin, and in Benzloe in the isle of Murray, Shetland; also at numerous localities in North America. It always contains from 1½ to 2½ per cent. ferric oxide, and sometimes stannic and tungstic oxides. A variety from Karingsbricka, in Sweden, contains a small percentage of chromium, and is the *titane oxydé chromifère* of Hauy.

Anatase, the purest form of native titanic oxide, is also dimetric; but its form is incompatible with that of rutile, from which it also differs in its mode of cleavage, specific gravity, hardness, and other physical characters. It usually occurs in very acute unmodified octahedrons, having the principal axis = 1·7723: and the angle P : P . in the terminal edges = 97° 55′, in the lateral edges = 136° 30′; sometimes also in a combination like *fig.* 222 (ii. 235). Respecting its physical characters, and the localities of its occurrence, see i. 289.

Brookite, or Arkansite, which consists of titanic oxide mixed with about 3 to 4½ per cent. ferric oxide, is trimetric, having the axes = 0·5941 : 1 : 0·5611. Angle P : P (brach.) = 135° 37′; P : P (macr.) = 101° 3′; P : P (basal) = 95° 22′; ∞P̄ : ∞P2 = 99° 50′. The crystals frequently exhibit the combination ∞P̆∞ . ∞P̄2 . P, like *fig.* 273 (ii. 148), together with other pyramids and horizontal prisms, and are generally flat between the predominant faces ∞P̆∞; often also of pyramidal character, exhibiting the faces P, ∞P̆2 equally developed, like *fig.* 272 without P̆∞. (Kopp's *Krystallographie*, 2te Aufl. p. 267). For the physical characters and the localities of brookite, see i. 680.

Preparation.—Pure titanic oxide may be prepared from rutile, or from the several varieties of titaniferous iron; in the latter case a considerable portion of the iron may be removed by repeatedly boiling the pulverised mineral with hydrochloric acid.

H. Rose fuses the very finely-divided mineral with 3 pts. potassic carbonate, and treats the fused potassic titanate thus obtained with cold water. The excess of alkali is thereby removed, together with silicate, manganate, and stannate of potassium; whilst acid titanate of potassium remains undissolved, together with ferric oxide, and perhaps a small quantity of stannic oxide. This residue is washed on a filter with cold water, till the wash-water begins to run through milky, and then dissolved in concentrated hydrochloric acid. To obtain pure titanic acid from this solution, Berthier dilutes it with a considerable quantity of water, passes sulphydric acid gas through it to precipitate any tin that may be present, and adds ammonia to the filtered liquid as long as any precipitate is thereby produced. This precipitate contains titanic acid contaminated with sulphide of iron, and perhaps, also, with sulphide of manganese. The liquid (which should smell strongly of ammonium-sulphide) is to be well shaken, and then left to clarify by subsidence; afterwards decanted, and the precipitate treated with concentrated aqueous sulphurous acid, which completely dissolves the sulphides of iron and manganese, but leaves the titanic acid undissolved; the latter may then be collected on a filter, and washed. The solution in hydrochloric acid may also be boiled with sulphite of ammonium as long as the resulting precipitate continues to increase; this precipitate then consists of pure titanic acid, the whole of the iron remaining in solution as ferrous salt. The precipitate must be washed on a filter, out of contact with the air, to prevent the formation and precipitation of ferric oxide, and then ignited. (Berthier.)

Wöhler melts finely-pulverised rutile, in a platinum-crucible standing in an earthen crucible, with twice its weight of potassic carbonate, and dissolves the pulverised mass in dilute hydrofluoric acid, whereupon potassio-titanic fluoride separates in crystals. To dissolve this compound, the mass is heated to the boiling-point, with addition of water, if necessary, and the liquid is filtered as hot as possible. If excess of hydrofluoric acid be avoided, the solution may be effected in a glass vessel. The potassio-titanic fluoride, which separates in shining crystalline scales on cooling, is washed on a filter with cold water, and purified by recrystallisation from boiling water; its hot aqueous solution is mixed with ammonia, which throws down titanate of ammonium; and the salt, when ignited, gives off ammonia, and is converted, with incandescence, into pure titanic oxide. This process is also well adapted for preparing titanic oxide from titaniferous iron. The mass obtained by fusing this mineral with carbonate of potassium, is dissolved in dilute hydrofluoric acid, which leaves behind the greater part of the iron, in the form of ferric oxide. After the greater part of the potassio-titanic fluoride has crystallised out, and been purified as above, the ferruginous mother-liquors are treated with chlorine-water, or an alkaline hypochlorite, to bring the iron to its highest stage of oxidation, and then treated in the cold with dilute ammonia, which precipitates all the ferric oxide, with only a small portion of titanic acid. This precipitate is quickly separated by filtration, and the liquid, when boiled, deposits titanate of ammonium, which may be converted, by ignition, into titanic oxide. (Wöhler, Ann. Ch. Pharm. lxxiv. 212.)

Merz (J. pr. Chem. xcix. 157; Bull. Soc. Chim. [1867], ii. 400) modifies Wöhler's process, by fusing rutile with four times its weight of potassic carbonate, digesting the fused mass in water, dissolving the residual acid titanate of potassium by the prolonged action of strong hydrochloric acid, and boiling the resulting solution in a leaden dish with fluoride of potassium. The liquid, on cooling, solidifies to a crystalline pulp of potassio-titanic fluoride, $2KF.TiF^4$, which may be purified by washing it with a little cold water, and precipitating traces of iron with a drop of ammonium-sulphide. It is then to be redissolved in boiling water, and the titanic acid precipitated by ammonia. Another method is to melt 1 pt. of rutile with 6 pts. acid sulphate of potassium, digest the fused mass in water, neutralise the liquid with soda, and heat it to the boiling-point, passing a stream of sulphydric acid gas through it, at the same time, to bring the iron to the state of ferrous salt. Titanic acid is then precipitated free from iron. (Merz.)

A very pure product is likewise obtained by decomposing titanic chloride (prepared by igniting a mixture of rutile and charcoal in chlorine-gas) with water or ammonia.

Anhydrous titanic oxide, obtained by ignition of the precipitated hydrate, forms reddish-brown lumps, which resemble rutile more nearly in lustre and colour, in proportion as they have been more strongly heated. It may be obtained in the crystalline form by passing the vapour of titanic chloride, mixed with steam, through a red-hot tube. According to Ebelmen (Compt. rend. xxxii. 330), it is obtained, in long needle-shaped crystals, by exposing the amorphous oxide, mixed with microcosmic salt, to a temperature somewhat below that of a porcelain furnace. According to Deville and Caron (*ibid.* xlvi. 704), titanic oxide crystallised in the form of rutile, may be obtained by decomposing a fusible titanate, especially stannous titanate, with silica at a high temperature. Deville finds also (Compt. rend. lii. 1864), that the amorphous oxide is converted into quadratic crystals (like rutile or anatase) by ignition in hydrochloric acid gas; the crystals are coloured blue, in consequence of the formation of a small quantity of a lower oxide. Hautefeuille (Compt. rend. lvii. 148; lx. 188; Jahresb. 1863, p. 212; 1864, p. 213) has also obtained crystallised titanic oxide by two methods: α. By decomposing titanic chloride or fluoride with aqueous vapour.—β. By crystallising amorphous titanic oxide in an atmosphere hydrochloric or hydrofluoric acid. The second method is, however, only a modification of the first, inasmuch as titanic chloride or fluoride is first formed, and subsequently decomposed. Under the influence of hydrochloric acid, the formation of crystallised titanic oxide takes place only at very high temperatures, and the crystals produced have always the form of rutile: under the influence of hydrofluoric acid, on the contrary, anatase is formed at the lowest red heat, brookite at a somewhat higher temperature, and rutile at very high temperatures.

Anhydrous titanic oxide melts only at the heat of the oxyhydrogen-blowpipe. It is completely insoluble in water, and in all acids excepting strong sulphuric acid. When heated in the pulverised state with this acid till the excess is driven off, the residue dissolves in water after cooling. By fusing the anhydrous oxide with six times its weight of acid potassic sulphate, a clear yellow mass is obtained, which dissolves perfectly in warm water, forming a clear solution.

Potassium and *sodium* reduce titanic oxide at a red heat, forming oxide of potassium or sodium, and a black mass, which does not acquire metallic lustre, and appears to be a mixture of metallic titanium with titanic or titanous oxide.—*Charcoal*, at white heat, reduces titanic oxide to the metallic state.—*Carbonic disulphide*, at a strong red heat, converts titanic oxide into sulphide of titanium, with simultaneous formation of carbonic oxide and carbonic dioxide (H. Rose).—When dry *chlorine-gas* is passed over an ignited mixture of titanic oxide and charcoal, titanic chloride is produced (p. 837). The oxide, fused with *alkaline carbonates*, yields titanates of alkali-metal.—*Ammonia-gas*, at a bright red heat, reduces titanic oxide to violet nitride of titanium, TiN^2 (Elsner.)

TITANIC HYDRATES OR ACIDS.—There appear to be two modifications of titanic acid, analogous in some respects to stannic and metastannic acid.—α. One of these, called titanic acid, is precipitated by ammonia from the solution of titanic chloride. It is a white powder, of specific gravity 3·8 to 3·93 according as it has been exposed to a higher or lower temperature. When heated, it assumes a transient yellow colour, becoming white again on cooling. Its conversion into titanic oxide, at a higher temperature, is attended with vivid incandescence.

Titanic hydrate dissolves easily in sulphuric, nitric, and hydrochloric acids, even when these acids are rather dilute; but these dilute solutions, when boiled, deposit metatitanic hydrate as a soft white powder, which, like anhydrous titanic oxide, is quite insoluble in all acids, excepting strong sulphuric acid. It also resembles the anhydrous oxide in not exhibiting incandescence when heated. Titanic hydrate, precipitated by ammonia, is also converted into insoluble metatitanic hydrate by washing with hot water, or drying at a high temperature.—According to R. Weber (Pogg. Ann. cxx. 287; Jahresb. 1863, p. 210), a recently prepared aqueous solution of titanic chloride is not clouded by sulphuric, nitric, or hydrochloric acid, but phosphoric, arsenic, and hydriodic acids give precipitates with it immediately, and acid potassic chromate after some time. If, however, the same solution be heated to the boiling-point for only a few seconds, it immediately yields, with hydrochloric, nitric, sulphuric, hydrofluoric, and even organic acids, a white precipitate of metatitanic hydrate, and with dichromate of potassium an immediate orange-yellow precipitate. The precipitated metatitanic hydrate dissolves completely in a large quantity of water, after the supernatant acid has been poured off, and is reprecipitated from the solution by acids. Metatitanic acid is also produced by oxidising metallic titanium with nitric acid of specific gravity 1·25. (Weber.)

Titanic hydrate dried over oil of vitriol, has, according to H. Rose, the composition, H^2TiO^3, or $H^2O.TiO^2$, but always contains a little ammonia which cannot be removed by washing. According to Merz (*loc. cit.*), titanic hydrate, after drying in the air for twenty-four hours, contains $H^2TiO^3.2H^2O$; after drying for several weeks, $H^2TiO^3.H^2O$. When dried over oil of vitriol, it quickly loses 1 at. water; and after being left for some time over oil of vitriol, or dried at 60°, it contains $3H^2TiO^3.TiO^2$, and finally, after drying at 100°, $H^2TiO^3.TiO^2$.

Metatitanic acid, deposited from its solution in sulphuric acid on boiling, contains, after prolonged drying in the air, or for twenty-four hours over oil of vitriol, H^2TiO^3; at 60°, it contains $H^2TiO^3.TiO^2$; at 100°, $H^2TiO^3.2TiO^2$; at 120°, $H^2TiO^3.3TiO^2$; at 160°, $H^2TiO^3\,4TiO^2$. In short, metatitanic acid gives up its water more easily than titanic acid. (Merz.)

When a solution of titanic hydrate in hydrochloric acid is subjected to dialysis, insoluble gelatinous titanic hydrate remains in the dialyser (Graham, Chem. Soc. J. xv. 256). A solution of gelatinous titanic hydrate in hydrochloric acid, prepared in the cold, and containing only 1 per cent. TiO^2, when left in the dialyser for some days, yields liquid titanic acid, which, when subjected to the action of alcohol and other liquids, form compounds analogous to those produced in like manner with silicic acid. (Graham, *ibid.* xvii. 325; Jahresb. 1864, p. 178.)

Titanic Salts.—Titanic hydrate acts as a weak base, and likewise as an acid, forming salts both with acids and with alkalis. The salts in which it plays the part of base are very unstable. The oxalate, phosphate, and sulphate have been partially studied by H. Rose (iv. 266, 584; v. 606); the sulphate, phosphate, and nitrate also by Merz (*loc. cit.*).

Nitrate.—Titanic hydrate dissolves in concentrated nitric acid, and the solution, evaporated over quicklime, first becomes covered with an iridescent film, and then yields a mass of shining laminæ, containing $5TiO^2.N^2O^5.6H^2O$, or $5H^2TiO^3.2HNO^3$.—This salt dissolves, though imperfectly, in cold water; the clear solution, heated to 100°, deposits titanic oxide. (Merz.)

Phosphate.—Phosphate of ammonium, added to a solution of titanic hydrate in hydrochloric acid, throws down nearly all the titanium in the form of a white gelatinous precipitate, which, when washed and dried, forms a porcelain-like mass, containing $2TiO^2.P^2O^5$. Merz is of opinion that the original precipitate contains $TiO^2.P^2O^5$, but that the phosphoric acid is partly removed by washing. (Merz.)

Sulphate.—The solution of titanic hydrate in sulphuric acid deposits the hydrate on dilution with water. Titanic hydrate, moistened with very strong sulphuric acid, becomes hot, and dissolves completely at the boiling heat. The solution gelatinises on cooling; but if part of the sulphuric acid is evaporated, there remains a white powder, which, when dried on a porous tile and then heated to 180°, contains $TiO^2.SO^3$ or $Ti^{iv}(SO^4)^2.TiO^2$. This salt gives up all its sulphuric acid at a red heat, or when treated with water. Hydrochloric acid dissolves it slowly in the cold, more easily when heated. (Merz.)

Titanates.—These salts have not been much studied. Most of them may be represented by the formulæ $M^4TiO^4 = 2M^2O.TiO^2$, and $M^2TiO^3 = M^2O.TiO^2$, analogous to the ortho- and meta-silicates. The titanates of calcium and iron occur as natural minerals. The titanates of the alkali-metals are formed by fusing titanic oxide with alkaline hydrates, carbonates, or acid sulphates—some of them also in the wet way. When finely pulverised and levigated, they dissolve in moderately warm, concentrated hydrochloric acid; but the greater part of the dissolved titanic acid is precipitated on boiling the solution with dilute acids. The neutral titanates of the alkali-metals, M^2TiO^3, are insoluble in water, but soluble in acids. The titanates of the earth-metals and heavy metals are insoluble, and may be obtained by precipitation. Hautefeuille has prepared several of them in crystals, the form and physical characters of which are, in some cases, identical with those of native titanates.

Titanate of Calcium, $CaTiO^3$.—This compound occurs native as *Perowskite*, in small cubes and other monometric forms, with cubic cleavage tolerably perfect. Hardness = 5·5. Specific gravity = 4·017. Lustre metallic adamantine, less bright on the cleavage-faces. Colour greyish to iron-black. Streak uncoloured to greyish. Opaque to subtranslucent.

Analyses:—*a.* From Achmatowsk, near Slatoust, in the Ural: black (Jacobson, Pogg. Ann. lxii. 596).—*b.* From the same: brown (Brooks, *ibid.*).—*c.* From the Findelen Glacier, near Zermatt (Damour, Ann. Min. [4], vi. 313).—*d.* From Vogtsburg on the Kaiserstuhl (Seneca, Ann. Ch. Pharm. civ. 371):

	a.	*b.*	*c.*	*d.*
Titanic oxide	58·96	59·00	59·23	59·12
Lime	39·20	36·76	39·92	35 81

Ferrous oxide	2·06	4·79	1·14	6·11
	100·22	100·66	100·29	101·04

Sphene (or titanite) is a silico-titanate of calcium, $CaSiO^3.CaTiO^3$ (p. 398). Respecting the artificial crystallisation of this compound and of calcic titanate, see TITANITE (p. 835). The artificial crystals of calcic titanate are said by Hautefeuille to be dimetric, whereas those of natural perowskite are monometric.

Titanates of Iron.—*a. Ferric titanate* is prepared by igniting finely-pulverised titaniferous iron (p. 846) with several times its weight of calcium-chloride, treating the fused mass with water to remove calcium-chloride and ferric chloride, and the residue with concentrated hydrochloric acid, which dissolves titanate of calcium. Ferric titanate then remains in long, thin, opaque needles, having a dark steel-grey colour and brilliant lustre. The crystals dissolve in melting acid potassic sulphate, forming a yellow liquid, which dissolves in water when cold; they are not altered by ignition in contact with the air, or in chlorine-gas, or by boiling with strong hydrochloric or sulphuric acid. (Liebig and Wöhler.)

β. Ferrous titanate, Fe^2TiO^4 or $2FeO.TiO^2$, is produced by fusing a mixture of 2 pts. titanic oxide, 5 pts. ferrous fluoride, and a large excess of sodium-chloride. On treating the fused product with a large quantity of water, removing the lighter substances by levigation, and heating the residue with dilute acetic acid till all laminar products are dissolved out, ferrous titanate remains in small prismatic crystals, having a dark-purple colour and the lustre of steel, and yielding an ochre-yellow powder. Their specific gravity is 4·37; they are not magnetic, and do not contain any ferric oxide. (Hautefeuille, Jahresb. 1864, p. 218.)

γ. The mineral called *Titaniferous Iron*, or *Ilmenite*—also, in certain varieties, *Crichtonite*, *Menakan*, *Menaccanite*, *Kibdelophane*, *Basanomelane*, *Hystatite*, *Washingtonite*, *Mohsite* — consists, sometimes of nearly pure ferrous titanate, sometimes of magnesio-ferrous titanate, sometimes of isomorphous mixtures of ferrous titanate with ferric oxide and ferroso-ferric oxide. It occurs in hemihedral, rhombohedral crystals (tetartohedral to the hexagonal type), isomorphous with iron-glance, having the principal axis = 1·3767, the angle R : R in the terminal edges = 85° 43′, and cleaving imperfectly parallel to R and oR; where the cleavage appears to be perfect, it is probable that combination-faces of different individuals exist (Kopp's *Krystallographie*, p. 211). The crystals are more or less tabular, often forming twins, united by the face R or oR; also implanted or imbedded, and united into groups, with scaly or granular structure. The mineral likewise occurs compact, in massive or in loose grains, and in the form of sand (titaniferous sand, titaniferous ironsand). Hardness = 5·0 to 6·0. Specific gravity = 4·6 to 5·0. Lustre submetallic. Colour iron-black to steel-grey. Streak black to brownish-red. Opaque. Fracture conchoïdal. Slightly magnetic. Before the blowpipe it is infusible, or becomes rounded in the reduction-flame at the edges only (the variety from Uddewalla, in Sweden, is fusible, according to Plantamour). With fluxes it gives the reactions of iron; the microcosmic salt bead becomes red or brown-red in the inner flame, and violet when treated with tin upon charcoal; many varieties give the manganese reaction with soda and nitre. The finely-pulverised mineral dissolves with more or less facility in hydrochloric acid, leaving a residue of titanic acid. The solution is generally yellow, containing both ferric and ferrous oxides. When heated with strong sulphuric acid, it acquires a dark-blue colour, which however disappears on addition of water, titanic acid then remaining undissolved.

Analyses:—A. *Containing little or no Ferric Oxide*.—*a*. From St. Christophe, near Bourg d'Oisans, in Dauphine: *Crichtonite*; specific gravity = 4·727 (Marignac, Ann. Ch. Phys. [3], xiv. 50).—*b*. Ingelsberg, near Hofgastein, in the Pinzgau: *Axotomous Iron-ore; Kibdelophane*: crystallised; non-magnetic, or very slightly magnetic; α. Specific gravity = 4·661 (v. Kobell, Schw. J. lxiv. 59, 245); β. Specific gravity = 4·689 (Rammelsberg, *Mineralchemie*, p. 408).—*c*. Rio Chico, province of Antioquia, New Granada: grains from the auriferous and platiniferous sand (Damour, Ann. Min. [3], li. 445).—*d*. Layton's Farm in the State of New York: crystallised, yielding a brown-black powder; non-magnetic; specific gravity = 1·293—4·313 (Rammelsberg):

	a.	*b*.		*c*.	*d*.
		α.	β.		
Titanic oxide	52·27	59·00	53·03	57·09	57·71
Ferric oxide	1·20	4·25	2·66		
Ferrous oxide	46·53	36·00	38·30	42·12	26·82
Manganous oxide	. .	1·65	4·30	0·80	0·90
Magnesia	. .	. .	1·65	. .	13·71
	100·00	100·90	99·94	100·01	99·14

If the small quantity of ferric oxide in *a* and *b*, β be deducted, and the magnesia and manganous oxide converted into their equivalents in ferrous oxide, the composition of these minerals may be nearly represented by the formula $FeO.TiO^2$ or $Fe''TiO^3$, which requires 53·72 TiO^2 and 46·28 FeO.—*c* is also nearly the same, but may be more closely represented by the formula $8FeO.9TiO^2$.—*d* is magnesio-ferrous titanate, $\left.\begin{matrix}\frac{1}{2}Mg\\ \frac{1}{2}Fe\end{matrix}\right\}TiO^3$, or $FeO.TiO^2 + MgO.TiO^2$, the calculated composition of which is 58·82 per cent. TiO^2, 26·47 FeO, and 14·71 MgO.

Shephard's *paracolumbite* (iv. 341) is, according to Pisani (Sill. Am. J. [2], xxxvii. 359), a ferrous titanate, difficult to separate from the matrix. It has a hardness = 4·5; specific gravity = 4·353; melts to a black magnetic bead, and gives by analysis:

TiO^2.	SiO^2.	Al^2O^3.	Fe^2O^3.	FeO.	MgO.	CaO.		
35·66	10·66	7·66	3·48	39·08	1·94	2·06	=	100·54

B. *Isomorphous Mixtures of Ferrous Titanate and Ferric Oxide.*—Titaniferous iron occurs, containing these compounds mixed in various proportions, between $9FeTiO^3.Fe^2O^3$ and $FeTiO^3.13Fe^2O^3$. The following formulæ must be regarded, not as representing definite compounds of ferrous titanate and ferric oxide, but merely as approximate expressions of the composition of the several varieties of the mineral as determined by analysis. For the discussion of the formulæ, see Rammelsberg's *Mineralchemie* (pp. 409—419).

a. From Egersund in Norway: massive; nearly black; specific gravity = 4·744—4·791 (Rammelsberg).—*b.* Krageröe, Norway: massive; specific gravity = 4·701 (Rammelsberg).—*c.* St. Paul's Bay, Canada: massive, granular, slightly magnetic; specific gravity = 4·56—4·66 (Hunt, Sill. Am. J. [2], xi. 231).—*d.* Cienaga, Province of Antioquia, New Granada (Damour, *loc. cit.*).—*e.* Ilmen Mountains, near Miask: *Ilmenite*; crystallised; powder brown-black; slightly magnetic (Rammelsberg).—*f.* Château-Richer, Canada: non-magnetic grains; specific gravity = 4·65—4·68 (Hunt).—*g.* Iserweise, in the Riesengebirge: *Iserin* (in part): granules varying in specific gravity, magnetic power, and composition; the analysis given is of a strongly magnetic grain (Rammelsberg).—*h.* Lichfield, Connecticut: *Washingtonite*; crystallised, slightly magnetic, yielding a black powder; specific gravity = 4·986 (Rammelsberg).—*i.* Eisenach, Thüringerwald: massive, yielding a black powder; not magnetic; specific gravity = 5·060 (Rammelsberg).—*j.* Uddewalla, Sweden: massive; slightly magnetic (Plantamour, J. pr. Chem. xxiv. 302).—*k.* Aschaffenburg: massive, laminar, mostly polar-magnetic; specific gravity = 4·78 (v. Kobell, *loc. cit.*).—*l.* Snarum, Norway: massive, accompanying serpentine and hydrotalcite; specific gravity = 4·943 (Rammelsberg).—*m.* St. Gothard: crystallised, yielding a black powder, non-magnetic; specific gravity = 5·187 (Rammelsberg).—*n.* Krageröe (so-called *iron-glance*); crystallised, slightly magnetic; specific gravity = 5·240 (Rammelsberg):

c. $2(FeO.TiO^2).3(FeO.2Fe^2O^3)$	8·27	51·81	37·22	2·03	0·78	=	100·11
d. $3(FeO.TiO^2).5(FeO.Fe^2O^3)$	15·28	48·71	36·01	. .	. .	=	100

A titaniferous iron-ore, imbedded in the diallage and augitic gabbro of Baste in the Harz, was found by Streng (Jahresb. 1862, p. 715) to contain 45·77 per cent. TiO^2, 44·55 Fe^2O^3, and 0·56 Cr^2O^3.

Magnetic Ironsand.—In many localities, black ferruginous grains occur, strongly attracted by the magnet, and partly in the form of regular octahedrons. In a specimen from the coast of Finland, Klaproth found 14 per cent., Maly 33 per cent., titanic oxide; Cordier has found, in similar specimens, from 11 to 16 per cent. titanic oxide. In an ironsand containing octahedrons from the Etna lavas, v. Walterhausen found 12·38 per cent. TiO^2 and 92·18 Fe^2O^3, which is an excess of 4·56, indicating the presence of ferrous oxide. A specimen of very fine ironsand from the Müggel Lake, near Berlin, yielding a black powder, and having a specific gravity of 5·075, was found by Rammelsberg to contain 5·20 per cent. TiO^2, 61·36 Fe^2O^3, 30·25 FeO, 1·23 MnO, and 0·48 MgO (= 98·52), which may be nearly represented by the formula $FeO.TiO^2.6(FeO.Fe^2O^3)$; but all these substances are, perhaps, merely mixtures of ferrous titanate and magnetic iron-ore, and the occurrence of definite proportions is merely accidental.

Titaniferous Iron containing Tantalum and Niobium.—In the diamond-sand of Diamantino in Brazil, Damour found black grains, yielding a dark-green powder, and having a specific gravity of 4·82, which contained 74·32 per cent. TiO^2, 6·67 Ta^2O^5, 2·04 SnO^2, and 16·97 FeO.

According to A. E. Nordenskjöld (Pogg. Ann. cxxii. 615), a mineral resembling titaniferous iron, or ilmenite, but containing niobic as well as titanic acid, occurs near the village of Torro, in Finland.

Titanate of Magnesium.—The *monobasic salt*, $MgTiO^3 = MgO.TiO^2$, is formed by heating 1 pt. titanic oxide to whiteness for a short time in a closed vessel, with 10 pts. chloride of magnesium, and a small quantity of sal-ammoniac. On treating the fused product, first with water containing acetic acid, then with pure water, the monomagnesic titanate remains, in shining six-sided crystals, probably belonging to the trimetric system, and coloured reddish by a trace of manganese. They scratch glass, and have a density of 3·91. If the chloride of ammonium be omitted in the preparation, the proportion of magnesium in the crystals will be somewhat greater (Hautefeuille).—The *dibasic salt*, $Mg^2TiO^4 = 2MgO.TiO^2$, is obtained by fusing 2 pts. titanic oxide, 1 pt. magnesia, and 40 pts. chloride of magnesium, and proceeding as in the preparation of the corresponding ferrous salt (p. 846). It forms very brilliant regular octahedrons, harder than glass and having a specific gravity of 3·42. (Hautefeuille.)

Manganous Titanates (Hautefeuille).—The *dibasic salt*, Mn^2TiO^4, is obtained by heating titanic oxide with fluoride of manganese, but always mixed with the laminar monobasic salt; neither of these compounds has been further examined.

Titanates of Potassium.—The *monobasic salt*, $K^2TiO^3 = K^2O.TiO^2$, is obtained by fusing titanic oxide with excess of potassic carbonate. Two fused layers are then formed, the upper containing the excess of carbonate, the lower the monobasic potassium-titanate. This salt forms a yellowish, fibrous, easily fusible mass, which is resolved by water into an insoluble acid salt, and a soluble salt containing a larger proportion of base.—The *acid salt* is a soft white powder, which, after ignition, contains 17·33 to 18·01 per cent. K^2O, and 82·67 to 81·99 TiO^2. On treating it with strong hydrochloric acid, and saturating the liquid with ammonia, a precipitate is formed, which, after ignition, contains 91·3 per cent. TiO^2 to 8·7 K^2O. (H. Rose.)

A *silico-titanate of potassium* is formed by igniting titanic oxide with excess of silica and excess of potassium-carbonate, and remains behind on treating the mass with water, which dissolves out carbonate and silicate of potassium. When moist, it dissolves easily in concentrated hydrochloric acid, forming a solution, which, when boiled, deposits flocks, somewhat soluble in water, and, when mixed with ammonia, yields a precipitate of silicic and titanic acids.

Titanates of Sodium.—The *monobasic salt*, $Na^2TiO^3 = Na^2O.TiO^2$, prepared like the corresponding potassium-salt, is resolved by water into an insoluble acid salt and free soda. This acid salt forms white sandy grains, containing 15·14 to 15·30 per cent. Na^2O, 74·73 to 75·47 TiO^2, and 10·13 to 9·23 water. On treating it with strong hydrochloric acid, and neutralising with ammonia, there remains a residue containing 96·2—96·56 per cent. TiO^2 to 3·8—3·44 Na^2O. (H. Rose.)

Titanate of Zirconium is precipitated on mixing the solutions of zirconic and titanic chlorides, and adding sulphate of potassium (Berzelius). Titanate of zirconium is one of the constituents of æschynite, fergusonite, and polymignite (i. 59; iv. 55, 687).

TITANIUM, OXYCHLORIDE OF. See p. 837.

TITANIUM, OXYFLUORIDE OF. See p. 840.

TITANIUM, SULPHIDE OF. TiS^2.—This, the only known sulphide of titanium, was discovered by H. Rose, who prepared it by slowly passing the vapour of carbonic disulphide over titanic oxide, very strongly ignited in a porcelain tube. Berzelius obtained it by igniting a mixture of 1 pt. pulverised rutile, 1 pt. dry carbonate of sodium, 1 pt. sulphur, and $\frac{1}{5}$ pt. charcoal, in a crucible lined with charcoal. Larger quantities are best prepared by passing a stream of dry sulphydric acid gas into a tubulated retort, containing titanic chloride, and having its neck connected with a glass tube laid horizontally over a furnace. As soon as this tube is heated to commencing redness, the retort is warmed to such a degree, that the sulphydric acid gas may pass into the tube saturated with the vapour of titanic chloride, at a temperature somewhat below the boiling-point of the latter. Hydrochloric acid vapours are then given off, and titanic sulphide remains in the tube. (Ebelmen, Ann. Ch. Phys. [3], xx. 285.)

Titanic sulphide thus prepared forms large, brass-yellow, metallically lustrous scales, which, when rubbed on the skin, cover it with a shining coating like mosaic gold. When ignited in the air, it burns readily, yielding titanic oxide and sulphurous oxide, which is volatilised. It detonates when heated with nitre. It is decomposed by dry chlorine-gas, the products being chloride of sulphur and chloride of titanium. With nitric acid it is resolved, with rise of temperature and disengagement of nitric oxide, into titanic oxide and sulphur. It is oxidised by warm nitromuriatic acid, yielding titanic acid (the greater part of which remains undissolved) and sulphuric acid. It dissolves slowly in hydrochloric acid, with evolution of sulphydric acid (H. Rose). At a tolerably strong red heat, it decomposes vapour of water with great facility, and is converted into titanic acid, with evolution of sulphydric acid and hydrogen-gas (Regnault). It is also gradually decomposed, with evolution of sulphydric acid, by exposure to moist air. When digested with aqueous potash, it is rapidly converted into white titanate of potassium, which is precipitated, and sulphydrate of potassium, which dissolves: $TiS^2 + 2KHO = TiO^2 + 2KHS$. (Rose.)

TITANIUM-GREEN. Ferrocyanide of titanium, precipitated by ferrocyanide of potassium from a solution of titanic chloride, has been recommended as an innocuous substitute for Schweinfurt-green and other arsenical green pigments; its colour, however, is far inferior to that of Schweinfurt-green. (Elsner, Dingl. pol. J. cv. 130.—Gentele, *ibid.* clx. 238; see also Jahresb. 1847–48, p. 1058.)

TITANIUM-SAND. Pulverulent titaniferous iron (p. 847).

TITANIUM-STEEL. See IRON, ALLOYS OF (iii. 370).

TITRATION. See ANALYSIS, VOLUMETRIC (i. 254).

TIZA. Boronatrocalcite, occurring in lumps in the deposits of nitrate of soda in Peru (i. 649).

TOBACCO. This substance, so extensively used for smoking, snuffing, and chewing, is prepared from the leaves of several species of *Nicotiana*—chiefly *N. Tabacum*, Virginia tobacco; *N. macrophylla*, Maryland tobacco; *N. rustica*, and *N. quadrivalvis*. The tobacco-plant is indigenous in tropical America, but thrives, under various climatic conditions, as high as the fiftieth degree of latitude, and is extensively cultivated in most countries within those limits.

The earliest chemical investigation of tobacco-leaves is that of Posselt and Reimann (Geiger's Mag. xxiv. 138; xxv. [2], 57), who found, in 1,000 pts.:

Nicotine	0·6	Malic acid, malates, and nitrates	9·7
Nicotianine	0·1	Other potassium-salts	1·2
Bitter extractive	28·7	Phosphate of calcium	1·7
Resin	2·7	Woody fibre, water, &c.	924·8
Albumin and Glutin	13·1		
Gum	17·4		

According to later investigations, the proportion of the poisonous alkaloïd, nicotine, is much larger. Schlösing (Ann. Ch. Phys. [3], xix. 230) found, in different sorts of tobacco, from 2 to 8 per cent. nicotine, the better and milder varieties, such as that from Havannah, containing the smallest quantity. (See NICOTINE, iv. 45.)

Another volatile constituent of tobacco is nicotianine, or tobacco-camphor (iv. 44). Vauquelin (Ann. Chim. lxxi. 139) found in tobacco an organic acid, which he regarded as malic acid, a result confirmed by Posselt and Reimann. Barral (Compt. rend. xxi. 1374) regarded it as a peculiar acid, designating it as nicotic acid. According to Goupel (Ann. Ch. Phys. [3], xvii. 503), the acid of tobacco-leaves is malic acid with a little citric acid: from 100 grms. of the dried leaves he obtained from 3 to 4 grms. of acid ammonium-malate.

Tobacco contains a considerable amount of inorganic constituents, the dried leaves yielding from 18 to 23 per cent. of ash. According to Casaseca (Ann. Ch. Phys. [3], xlv. 479), good Havannah tobacco contains from 16 to 16·8 per cent. ash; inferior sorts from 17·8 to 19·4 per cent.; the latter contained a trace of iodine, which was not found in the better kinds. Vogel (Repert. Pharm. [1858], vi. 100) found, in Turkish tobacco from various localities, 17 to 23 per cent.; in Russian, 21·9 to 24·9; in Grecian, 19 per cent. ash. Will and Fresenius (Ann. Ch. Pharm. l. 387) have analysed the ash of several varieties of Hungarian tobacco (No. i. to viii. of the following table), and Merz (*ibid.* lxxix. 109) has analysed that of tobacco grown in the neighbourhood of Nürnberg (No. ix.):—

Ash of Tobacco.

	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.
Ash per cent. of dry substance:									
Leaves	18·9	19·8	23·0	21·1	23·3	23·3	22·8	27·3	
Stalks	22·9	32·5	19·8						
Potash	29·1	18·8	8·2	19·5	9·7	9·3	10·3	11·2	26·9
Soda	2·2	. .	. .	0·3	. .	. .	. .	. .	2·7
Lime	27·7	27·8	42·8	44·5	49·3	49·4	39·5	47·0	39·5
Magnesia	7·2	15·7	13·9	11·1	14·6	15·6	15·0	12·8	9·6
Chloride of sodium	0·9	11·4	2·2	3·5	4·6	3·2	6·4	2·6	9·6
Chloride of potassium	. .	3·9	8·5	. .	4·4	3·3	3·0	3·0	
Ferric phosphate	8·8	6·8	6·1	4·3	5·2	6·7	7·5	6·3	4·2
Phosphate of calcium	. .	. .	. .	6·0					
Sulphate of calcium	6·4	10·1	8·0	5·6	6·7	6·1	9·4	5·1	
Silica	17·6	6·0	9·3	5·1	5·5	6·3	8·3	12·0	4·5
Sulphuric anhydride	. .	. .	. .	. .	. .	. .	. .	. .	2·8
	99·9	100·5	99·0	99·9	100·0	99·9	99·4	100·0	99·8

Schlösing (J. pr. Chem. lxxxi. 148) has determined the quantities of potash, lime, magnesia, sulphuric acid, and chlorine in tobacco grown on various soils. In the air-dried leaves of twelve different sorts, he found 90 pts. of dry substance and 10 pts. water:—

	I.	II.	III.	IV.	V.	VI.	VII.	VIII.	IX.	X.	XI.	XII.
Potash	1·0	1·0	2·6	1·7	2·1	1·6	2·2	2·5	1·1	0·8	1·4	2·0
Lime	7·7	7·5	6·6	7·2	6·2	7·3	6·2	6·6	8·5	8·3	7·7	7·4
Magnesia	1·0	0·8	0·8	0·7	0·6	. .	0·6	. .	1·0	1·1	0·9	0·3
Sulphuric anhydride	1·0	0·9	1·0	0·9	0·8	1·0	0·8	1·0	0·8	0·8	1·0	1·0
Chlorine	0·7	0·5	0·4	1·6	0·4	0·4	0·4	0·5	1·8	1·7	. .	0·5

The combustibility of tobacco is influenced to a considerable extent by the proportion of the potash and lime contained in it, and the manner in which these bases are combined with acids. The ash of the more combustible tobaccos is comparatively rich in carbonate of potassium, showing that in these tobaccos the potash is in combination with organic acids; whereas the ash of the less combustible tobaccos contains sulphate and chloride of potassium, together with carbonate of calcium, instead of carbonate of potassium, showing that in these tobaccos the organic acids are combined with lime. A slowly-burning tobacco may be rendered more combustible by adding to it an organic potassium-salt, in such quantity that the amount of potash in the ash may be more than equivalent to the sulphuric and hydrochloric acids present; and, on the other hand, the combustibility of tobacco may be diminished by mixing it with such a quantity of sulphate or chloride of magnesium, calcium, or ammonium, that the amount of hydrochloric or sulphuric acid in the ash may be more than equivalent to the potash, so that the ash will not contain any potassic carbonate. (Schlösing.)

Tobacco always contains nitrates. According to Schlösing, these salts are most abundant in the midrib of the leaf, which, in different varieties, contains from 0·15 to 6·1 per cent. nitric acid, the leaf, deprived of its midrib, containing from 0·02 to 2·0 per cent. The ready inflammability of tobacco, and its capability of burning with a smouldering flame, are due, in great part, to this large amount of nitrates.

In the smoking of tobacco an imperfect combustion takes place, one part of the tobacco burning in contact with the air, and producing by its combustion a quantity of heat sufficient to decompose the remainder by destructive distillation, producing water and tar (oil of tobacco), which, when the tobacco is smoked in a pipe, condense as liquid products. Tobacco-smoke consists partly of permanent gases—namely, carbonic oxide, carbonic dioxide, and perhaps also one or more hydrocarbons—partly of condensable vapours, including, according to Zeise (Ann. Ch. Pharm. xlvii. 212), ammonia, butyric acid, probably also acetic acid, paraffin, empyreumatic oil, and resin, but no creosote. Melsens found nicotine, the presence of which is, indeed, sufficiently indicated by the narcotic action of the tobacco-smoke. Vogel (Repert. Pharm. vi. 1 155; vii. 97, 514; viii. 145) found sulphydric and hydrocyanic acids, and determined their quantity, as well as that of the ammonia: from 100 grms. tobacco he obtained 0·7 to 2·8 grms. ammonia. The proportions of the several constituents of tobacco-smoke vary, of course, according to the freedom of access of air during the combustion: hence the difference in the action of tobacco, according as it is smoked in pipes or in cigars.

Respecting the manufacture of tobacco and snuff, see *Ure's Dictionary of Arts*, &c., iii. 907; *Handw. d. Chem.* viii. 462.

TOBACCO-CAMPHOR. Syn. with Nicotianine (iv. 44).

TOBACCO-OIL. The empyreumatic oil produced in the destructive distillation of tobacco.

TOBACCO-SEED OIL. Tobacco-seeds are said to yield, by pressure, about 36 per cent. of a greenish-yellow, mild, inodorous oil, of specific gravity 0·923 at 15°, solidifying at −25°, and quickly drying when exposed to the air.

TODDALEA. See Lopez-root (iii. 733).

TOLALLYL-SULPHIDE. $(C^7H^5)^2S$.—A product obtained, together with others, by the dry distillation of sulphide or disulphide of benzyl. After repeated crystallisation from alcohol, it forms a white crystalline powder, very sparingly soluble in alcohol, more easily in ether or in benzene, and melting at 143°—145°. (Märcker, Ann. Ch. Pharm. cxxxvi. 75.)

TOLENE. $C^{10}H^{16}$.—The oily constituent of tolu-balsam (i. 498). The balsam distilled with water yields 0·2 per cent. of the oil (Deville), 1·1 per cent. (Scharling), which may be rectified over hydrate of potassium. Scharling further treats it with potassium, and then rectifies it again.

Tolene is a colourless very mobile liquid, having a pungent odour, and a specific gravity of 0·858 at 10° (E. Kopp). It boils at 170° (Deville; Scharling), at 154°—160° (E. Kopp). Vapour-density = 5·1 (Deville). When exposed to the air, it quickly takes up oxygen, and becomes resinised; it likewise oxidises when boiled with water and mercuric oxide, forming a small quantity of carbonic anhydride; but the oxidation is not easily completed, and does not yield any well-characterised products (Schorling). Tolene mixed with bromine forms a black-brown tarry liquid.

TOLID. A name sometimes applied to benzyl, C^7H^7.

TOLIN. Syn. with Toluene.

TOLU-BALSAM. See Balsams (i. 498).

TOLUAMIC ACID. $C^8H^9NO^2$.—Syn. with Oxytoluamic Acid (iv. 321).

TOLUENE, or **TOLUOL.** C^7H^8.—Syn. with Benzylic Hydride, under which name the compound has been already described (i. 574).

Besides the modes of formation there mentioned, it is produced:—*α*. By distilling vulpic or oxytolic acid with potassium-hydrate (Möller and Strecker, Ann. Ch. Pharm. cxiii. 69).—*β*. In the dry distillation of several organic substances, namely of dragon's-blood (Glénard and Boudault, *ibid.* liii. 325), wood (Cahours; Volckel), and coal (Mansfield), being, in fact, a constant constituent of coal-tar oil.—*γ*. By the action of methyl-iodide and sodium on monobromobenzene (Fittig and Tollens):

$$C^6H^5Br + CH^3I + Na^2 = NaBr + NaI + C^7H^8.$$

This and the following mode of formation show that toluene may be regarded as methylic benzene, $C^6H^5(CH^3)$, or phenyl-methyl, $C^6H^5.CH^3$.

δ. By the mutual action of benzene and methylic hydride (marsh-gas) in the nascent state, as when an intimate mixture of 2 pts. acetate and 1 pt. benzoate of sodium is subjected to dry distillation (Berthelot, Bull. Soc. Chim. [1867], i. 116):

$$C^6H^6 + CH^4 = C^7H^8 + H^2.$$

Other homologues of benzene—namely, xylene, C^8H^{10}, and cumene, C^9H^{12}—are produced at the same time by similar reactions. The formation of these homologues of benzene in the destructive distillation of coal is probably due, in like manner, to the reaction of benzene and marsh-gas at the moment of their elimination from certain constituents of the coal.—ε. Toluene is found, together with many other hydrocarbons, in Rangoon tar (iv. 3).

Toluene is most advantageously prepared from coal-naphtha; in fact, the coal-naphtha now occurring in commerce consists mainly of toluene and its higher homologues. It may be obtained tolerably pure by collecting the portion of the naphtha which distils between 100° and 120°, agitating it with half its weight of strong sulphuric acid, and rectifying it repeatedly, collecting apart the portion which distils between 108° and 110°.

Toluene has a specific gravity of 0·8654 at 15° (Mendelejef, Jahresb. 1860, p. 7); 0·8824 at 0°, 0·8720 at 15° (Warren, *ibid.* 1865, p. 525). It boils at 110·3° (corrected). (Warren.)

Toluene-vapour passed through a porcelain tube heated to bright redness, is decomposed, yielding uncondensable gases and a tarry liquid, which may be resolved, by two series of rectifications, into benzene, C^6H^6; unaltered toluene, C^7H^8; naphthalene, $C^{10}H^8$; benzyl, $C^{14}H^{14}$, and a hydrocarbon apparently isomeric therewith; anthracene, $C^{14}H^{10}$, chrysene, $C^{18}H^{12}$; and hydrocarbons of higher atomic weight. The formation of these hydrocarbons may be represented by the equations:

$$\underset{\text{Toluene.}}{2C^7H^8} = \underset{\text{Benzyl.}}{C^{14}H^{14}} + H^2.$$

$$\underset{\text{Toluene.}}{4C^7H^8} = \underset{\text{Benzene.}}{3C^6H^6} + \underset{\text{Naphthalene.}}{C^{10}H^8} + 3H^2.$$

$$\underset{\text{Toluene.}}{2C^7H^8} = \underset{\text{Anthracene.}}{C^{14}H^{10}} + 3H^2.$$

$$\underset{\text{Toluene.}}{18C^7H^8} = \underset{\text{Chrysene.}}{7C^{18}H^{12}} + 30H^2.$$

Or the chrysene may be formed from benzene, according to the equation $3C^6H^6 = C^{18}H^{12} + 3H^2$. (Berthelot, Bull. Soc. Chim. [1837], i. 218.)

Toluene oxidised with dilute nitric acid yields oxytolic acid, $C^7H^6O^3$ (Fittig, iv. 321); but fuming nitric acid converts it into nitrodracylic acid, $C^7H^4(NO^2)O^2$, isomeric with nitrobenzoic acid (iv. 60).

Derivatives of Toluene.

The rational formula of toluene, $C^6H^5.CH^3$, indicates the existence of two series of substitution-products, according as the hydrogen of the phenyl-molecule, or of the methyl-molecule, is replaced by other radicles, *e.g.*:

$C^6H^4Cl.CH^3$ Monochlorotoluene.	$C^6H^5.CH^2Cl$ Benzylic chloride.
$C^6H^4(HO).CH^3$ Cresol.	$C^6H^5.CH^2(HO)$ Benzylic alcohol.
$C^6H^4(NH^2).CH^3$ Toluidine.	$C^6H^5.CH^2(NH^2)$ Benzylamine.

These isomeric derivatives differ considerably from one another in their properties. Those in the left-hand column, formed by replacement of hydrogen in the phenyl-molecule, are comparatively stable and indifferent compounds, like those derived in like manner from benzene, C^6H^6; whereas those in the right-hand column, formed by replacement of hydrogen in the methyl-molecule, are more active bodies, capable of easily exchanging their chlorine, hydroxyl, &c. for other radicles by double decomposition. Thus benzylic alcohol, treated with hydrochloric acid, yields benzylic chloride; this compound, heated with alcohol ammonia, yields benzylamine; the chloride is also easily converted into the acetate, cyanide, &c. by treatment with the corresponding potassium-salts. In short, these last-mentioned toluene-derivatives exhibit reactions exactly like those of the corresponding compounds of the fatty series, and may, in like manner, be supposed to contain an alcohol-radicle, C^7H^7, called benzyl or tolyl, and referred to the water-type, ammonia-type, &c.: *e.g.*, benzylic chloride $= C^7H^7.Cl$; benzylic alcohol $= C^7H^7.H.O$; benzylamine $= C^7H^7.H^2.N$, &c.

Amidotoluene, $C^7H^9N = C^7H^7(NH^2) = C^6H^4(NH^2).CH^3$. Syn. with TOLUIDINE (p. 865).

Azotoluenes. See AZOTOLUIDINES (p. 867).

Bromotoluenes. (Glinzer and Fittig, Ann. Ch. Pharm. cxxxiii. 47; cxxxvi.

301.—Kekulé, Ann. Ch. Pharm. cxxxvii. 183, 192.—Lauth and Grimaux, Bull. Soc. Chim. [1866], i. 647; [1867], i. 108).—Bromine acts directly upon toluene, forming monobromotoluene, or benzylic bromide, according as the reaction takes place at low or at high temperatures. Higher substitution-products appear to be formed at the same time, but they have not been isolated.

MONOBROMOTOLUENE, $C^7H^7Br = C^6H^4Br.CH^3$, is prepared by gradually adding bromine to toluene kept cool and in excess, leaving the liquid to itself for a few days, and purifying the product by agitation with potash-ley, and rectification over solid potash. It is a colourless liquid, having a faint, not unpleasant odour when cold, but (according to Lauth and Grimaux) extremely irritating to the eyes when heated; according to Fittig and Kekulé, on the other hand, pure bromotoluene does not exhibit this irritating property. It has a specific gravity of 1·4092 at 15°, and boils at 179° (Glinzer and Fittig); at 181° (Lauth and Grimaux); at 182·5°—183° (Kekulé). It is a very stable compound, and is not decomposed by heating with ethylate of sodium, acetate of potassium, acetate of silver, cyanide of potassium, or alcoholic ammonia.

Benzylic bromide, $C^7H^7.Br = C^6H^5.CH^2Br$, is easily obtained by the action of gaseous hydrobromic acid, or the saturated aqueous acid, on benzylic alcohol; also by the action of bromine on boiling toluene. It is a colourless liquid, fuming slightly in the air, and boiling at 198°—199° (Kekulé); at 202°, according to Lauth and Grimaux; but their product was probably impure. It has at first a pleasant aromatic odour, but exposure to its vapour produces a copious flow of tears. It gives up its chlorine, by double decomposition, with great facility, being rapidly attacked by acetate of potassium, acetate of silver, cyanide of potassium, alcoholic solution of hydrate or sulphydrate of potassium, and alcoholic ammonia, yielding benzyl-compounds in all cases.

DIBROMOTOLUENE, $C^7H^6Br^2$.—Toluene is capable of yielding three dibrominated derivatives, corresponding to the dichlorinated toluenes (p. 854); but the only one hitherto obtained in the pure state is that which corresponds to chlorobenzol, viz. dibromobenzol, or bromide of benzylidene, $C^7H^6.Br^2 = C^6H^5.CBr^2H$, which is produced by the action of phosphoric pentabromide on benzoic hydride (bitter-almond oil). It is decomposed by distillation under the ordinary atmospheric pressure, but distils easily in a vacuum. When treated with sodium, or sodium-amalgam, it yields toluene and benzyl, $C^{14}H^{14}$ (Michaelson and Lippmann, Ann. Ch. Pharm. Supp. iv. 113). See p. 870.

Lauth and Grimaux have likewise obtained other brominated derivatives of toluene, but not in sufficient quantity for accurate investigation.—*α*. If the first drops of bromine be added very slowly to the toluene, no disengagement of hydrobromic acid takes place; but the mixture, which remains colourless, deposits a small quantity of a compound in hexagonal tables, perhaps resulting from the direct fixation of bromine on toluene.—*β*. When the crude bromotoluene is distilled till the boiling-point rises to 185°, a black viscid residue is left, extremely irritating to the eyes, and becoming filled, after a few days, with needle-shaped crystals, difficult to purify from a thick viscid substance with which they are impregnated.—*γ*. When toluene was treated with 2 at. bromine (for the preparation of dibromotoluene), a thick liquid was formed, which remained coloured even after the excess of bromine had been removed. This liquid, when distilled, began to boil at 187°, continued to give off hydrobromic acid till the temperature rose to 210°, and left a black residue which did not solidify.

Chlorotoluenes.—The action of chlorine upon toluene gives rise to a number of substitution-products, differing in constitution according as the reaction takes place at high or at low temperatures. Compounds isomeric with some of these are also obtained from benzylic alcohol.

Of the two monochlorinated compounds whose existence is indicated by theory, viz. monochlorotoluene and benzylic chloride, the former is produced at low, the latter at high temperatures, as is the case with the corresponding bromine-compounds.

MONOCHLOROTOLUENE, $C^6H^4Cl.CH^3$.—Deville obtained this compound by saturating toluene (prepared from tolu-balsam) with chlorine (i. 574); and Beilstein and Geitner have lately shown (Ann. Ch. Pharm. cxxix. 331; Bull. Soc. Chim. [1867], i. 251), that it is always produced when cooled toluene is treated with chlorine. As, however, the action is attended with rise of temperature, benzylic chloride is apt to be produced at the same time; but pure chlorotoluene may be obtained by treating the crude product with any of the reagents by which benzylic chloride is decomposed. Pure chlorotoluene, free from benzylic chloride, is also produced at once by treating toluene with chlorine in presence of iodine. The same compound is probably formed by the action of chlorine on cresol.

titanate, with silica at a high temperature. Deville finds also (Compt. rend. lii. 1864), that the amorphous oxide is converted into quadratic crystals (like rutile or anatase) by ignition in hydrochloric acid gas; the crystals are coloured blue, in consequence of the formation of a small quantity of a lower oxide. Hautefeuille (Compt. rend. lvii. 148; lx. 188; Jahresb. 1863, p. 212; 1864, p. 213) has also obtained crystallised titanic oxide by two methods: *α.* By decomposing titanic chloride or fluoride with aqueous vapour.—*β.* By crystallising amorphous titanic oxide in an atmosphere hydrochloric or hydrofluoric acid. The second method is, however, only a modification of the first, inasmuch as titanic chloride or fluoride is first formed, and subsequently decomposed. Under the influence of hydrochloric acid, the formation of crystallised titanic oxide takes place only at very high temperatures, and the crystals produced have always the form of rutile: under the influence of hydrofluoric acid, on the contrary, anatase is formed at the lowest red heat, brookite at a somewhat higher temperature, and rutile at very high temperatures.

Anhydrous titanic oxide melts only at the heat of the oxyhydrogen-blowpipe. It is completely insoluble in water, and in all acids excepting strong sulphuric acid. When heated in the pulverised state with this acid till the excess is driven off, the residue dissolves in water after cooling. By fusing the anhydrous oxide with six times its weight of acid potassic sulphate, a clear yellow mass is obtained, which dissolves perfectly in warm water, forming a clear solution.

Potassium and *sodium* reduce titanic oxide at a red heat, forming oxide of potassium or sodium, and a black mass, which does not acquire metallic lustre, and appears to be a mixture of metallic titanium with titanic or titanous oxide.—*Charcoal*, at white heat, reduces titanic oxide to the metallic state.—*Carbonic disulphide*, at a strong red heat, converts titanic oxide into sulphide of titanium, with simultaneous formation of carbonic oxide and carbonic dioxide (H. Rose).—When dry *chlorine-gas* is passed over an ignited mixture of titanic oxide and charcoal, titanic chloride is produced (p. 837). The oxide, fused with *alkaline carbonates*, yields titanates of alkali-metal.—*Ammonia-gas*, at a bright red heat, reduces titanic oxide to violet nitride of titanium, TiN^2 (Elsner.)

TITANIC HYDRATES OR ACIDS.—There appear to be two modifications of titanic acid, analogous in some respects to stannic and metastannic acid.—*α.* One of these, called titanic acid, is precipitated by ammonia from the solution of titanic chloride. It is a white powder, of specific gravity 3·8 to 3·93 according as it has been exposed to a higher or lower temperature. When heated, it assumes a transient yellow colour, becoming white again on cooling. Its conversion into titanic oxide, at a higher temperature, is attended with vivid incandescence.

Titanic hydrate dissolves easily in sulphuric, nitric, and hydrochloric acids, even when these acids are rather dilute; but these dilute solutions, when boiled, deposit metatitanic hydrate as a soft white powder, which, like anhydrous titanic oxide, is quite insoluble in all acids, excepting strong sulphuric acid. It also resembles the anhydrous oxide in not exhibiting incandescence when heated. Titanic hydrate, precipitated by ammonia, is also converted into insoluble metatitanic hydrate by washing with hot water, or drying at a high temperature.—According to R. Weber (Pogg. Ann. cxx. 287; Jahresb. 1863, p. 210), a recently prepared aqueous solution of titanic chloride is not clouded by sulphuric, nitric, or hydrochloric acid, but phosphoric, arsenic, and hydriodic acids give precipitates with it immediately, and acid potassic chromate after some time. If, however, the same solution be heated to the boiling-point for only a few seconds, it immediately yields, with hydrochloric, nitric, sulphuric, hydrofluoric, and even organic acids, a white precipitate of metatitanic hydrate, and with dichromate of potassium an immediate orange-yellow precipitate. The precipitated metatitanic hydrate dissolves completely in a large quantity of water, after the supernatant acid has been poured off, and is reprecipitated from the solution by acids. Metatitanic acid is also produced by oxidising metallic titanium with nitric acid of specific gravity 1·25. (Weber.)

Titanic hydrate dried over oil of vitriol, has, according to H. Rose, the composition, H^2TiO^3, or $H^2O.TiO^2$, but always contains a little ammonia which cannot be removed by washing. According to Merz (*loc. cit.*), titanic hydrate, after drying in the air for twenty-four hours, contains $H^2TiO^3.2H^2O$; after drying for several weeks, $H^2TiO^3.H^2O$. When dried over oil of vitriol, it quickly loses 1 at. water; and after being left for some time over oil of vitriol, or dried at 60°, it contains $3H^2TiO^3.TiO^2$, and finally, after drying at 100°, $H^2TiO^3.TiO^2$.

Metatitanic acid, deposited from its solution in sulphuric acid on boiling, contains, after prolonged drying in the air, or for twenty-four hours over oil of vitriol, H^2TiO^3; at 60°, it contains $H^2TiO^3.TiO^2$; at 100°, $H^2TiO^3.2TiO^2$; at 120°, $H^2TiO^3.3TiO^2$; at 160°, $H^2TiO^3.4TiO^2$. In short, metatitanic acid gives up its water more easily than titanic acid. (Merz.)

Chlorobenzylic chloride, $C^6H^4Cl.CH^2Cl$ (often called *Dichlorotoluene*).—This compound is produced, as above stated, by the action of chlorine on benzylic chloride, or on monochlorotoluene, and therefore also by the action of chlorine on toluene. Beilstein (Ann. Ch. Pharm. cxvi. 336) saturates toluene in diffused daylight with chlorine, either at ordinary or at higher temperatures; distils, collecting the product which passes over between 186° and 220°; and rectifies it several times. It is difficult to obtain a product of constant boiling-point; that of the pure compound appears to be somewhat below 200°. (Compare Lauth and Grimaux, Bull. Soc. Chim. [1867], i. 108).

Chlorobenzylic chloride is a colourless, strongly refracting liquid, the vapours of which excite tears. It easily gives up one-half of its chlorine, but the other half is more fixed, as in true substitution-products.—With *alcoholic potash*, it yields a chlorinated oil, $C^9H^{11}ClO$, boiling at 215°—220°, which is the ethylic ether of monochlorinated benzyl-alcohol, $\left.\begin{matrix}C^7H^6Cl\\H\end{matrix}\right\}O$ (Naquet, Ann. Ch. Pharm. Suppl. ii. 249); and with *alcoholic sulphide of potassium*, a beautifully crystallised compound, which is the sulphydrate or mercaptan corresponding to the same alcohol, $\left.\begin{matrix}C^7H^6Cl\\H\end{matrix}\right\}S$ (Beilstein). Chlorobenzylic chloride is not converted into benzoic hydride by heating with water to 130°—140°; neither does it yield benzoic acid on exposure to moist air. (Naquet.)

Chlorobenzol, $C^7H^6Cl^2 = C^6H^5.CCl^2H$. (Cahours, Ann. Ch. Pharm. lxx. 39; *ibid.* Suppl. ii. 253, 306.—Wicke, Ann. Ch. Pharm. cii. 356.—Engelhardt, Jahresb. 1857, p. 470.—Naquet, Ann. Ch. Pharm. Suppl. ii. 249, 258.)—This compound, already described as chloride of benzylene, $(C^7H^6)''Cl^2$ (i. 577), is produced by the action of phosphoric pentachloride on benzoic hydride. According to Lauth and Grimaux (Bull. Soc. Chim. [1866], ii. 347), it is also formed, together with benzylic and chlorobenzylic chlorides, when toluene is distilled in a current of chlorine, and remains in the retort, together with chlorobenzylic chloride, after the benzylic chloride has been distilled off.

Chlorobenzol is a colourless, strongly refracting oil, having a faint odour in the cold, strongly irritating when heated, and boiling at 206°. Specific gravity = 1·295 at 16°. It gives up the whole of its chlorine with great facility, in exchange for *oxygen*, producing benzoic hydride, the reaction being, in fact, the opposite of that by which it is produced:

$$C^6H^5.CCl^2H + H^2O = C^6H^5.COH + 2HCl.$$

Thus, when heated with water or aqueous potash to 120°—130°, it is converted into benzoic hydride; and in contact with moist air, it yields benzoic acid, evidently resulting from oxidation of the previously formed hydride (Cahours). Heated with *alcoholic sulphydrate of potassium*, it yields the sulphur-analogue of benzoic hydride, C^7H^6S, commonly called *sulphobenzol* (Cahours).—*Sodium* decomposes it, forming chloride of sodium, and benzylene, C^7H^6. When its vapour is directed upon ignited *soda-lime*, benzene is formed, together with carbonic oxide and hydrochloric acid (Limpricht, Bull. Soc. Chim. 1866, ii. 467):

$$C^7H^6Cl^2 + H^2O = C^6H^6 + CO + 2HCl.$$

Trichlorotoluene, and its isomers.—Of the numerous isomeric compounds which might be included under the empirical formula $C^7H^5Cl^3$, only two are known with certainty, viz.:

$C^6H^3Cl^2.CH^2Cl$	and	$C^6H^5.CCl^3$.
Dichlorobenzylic chloride.		Benzotrichloride.

The true trichlorotoluene, $C^6H^2Cl^3.CH^3$, may perhaps be formed by the action of chlorine on toluene, but it has not been isolated.

Dichlorobenzylic chloride, $C^6H^3Cl^2.CH^2Cl$.—This compound is formed by the prolonged action of chlorine upon toluene, and separated by repeated fractional distillation (Naquet, Ann. Ch. Pharm. Suppl. ii. 248). It is commonly regarded as trichlorotoluene, but, according to Kekulé (*Lehrbuch*, ii. 561), it should rather be regarded as a substitution-derivative of benzylic chloride, inasmuch as its formation is preceded by that of monochlorobenzylic chloride. It is a colourless liquid, having a pungent odour, and a specific gravity of 1·44. Under the ordinary atmospheric pressure, it boils, with partial decomposition, at 240°; but under a reduced pressure of 10 mm. of mercury, it distils without decomposition at 135°—143°. It may be heated with water to 200° for several days, without forming benzoic acid; according to Naquet, however, it yields that acid when strongly heated with alcoholic potash.

Benzotrichloride, or *Chlorinated Chlorobenzol*, $C^6H^5Cl^3$. (Schischkoff and Rosing, Jahresb. 1858, p. 279.—Cahours, Ann. Ch. Pharm. Suppl. ii. 306.—

Limpricht, *ibid.* cxxxiv. 55, cxxxv. 80; Bull. Soc. Chim. 1866, ii. 468.)—This substance, analogous in composition and properties to chloroform, was discovered, in 1848, by Schischkoff and Rosing, who obtained it by the action of phosphoric pentachloride on benzoic chloride, to which it is related in the same manner as chlorobenzol to benzoic hydride:

$$\underset{\text{Benzoic chloride.}}{C^6H^5.COCl} + PCl^5 = \underset{\text{Benzotrichloride.}}{C^6H^5.CCl^3} + POCl^3.$$

To prepare it, benzoic chloride is heated with pentachloride of phosphorus to 180° for 48 hours. It is also formed by the action of chlorine on chlorobenzol. (Cahours.)

Benzotrichloride is a liquid smelling like benzoic chloride, and boiling at 215°—218°. It is insoluble in water, by which, however, it is converted (slowly in the cold, quickly at 140°) into benzoic acid.—*Sodium* does not act upon it, even at the boiling heat.—Dry *silver-oxide* converts it into benzoic anhydride; with silver-oxide moistened with alcohol, it forms benzoic acid and benzoic ether. When heated with *alcohol* to 130°, it likewise yields benzoic acid, according to the following equation:

$$C^7H^5Cl^3 + 3(C^2H^5.H.O) = C^7H^6O^2 + 3C^2H^5Cl + H^2O.$$

Sulphydrate of potassium in alcoholic solution acts upon it, with evolution of heat, forming a crystallisable sulpho-compound, not yet investigated.

Benzotrichloride heated to 140°, with aqueous *ammonia*, yields a large quantity of benzonitrile, behaving in this respect just like chloroform:

$$C^7H^5Cl^3 + NH^3 = C^7H^5N + 3HCl.$$

It also reacts like chloroform with *ethylate of sodium*, forming a compound (boiling at 220°—225°), analogous to the so-called tribasic formic ether:

$$C^7H^5Cl^3 + 3C^2H^5NaO = 3NaCl + \left.\begin{matrix}(C^7H^5)'''\\(C^2H^5)^3\end{matrix}\right\}O^3.$$

With *acetate of silver*, it forms, in the first instance, a compound, $C^{13}H^{14}O^6$, which may be regarded either as an acetyl-compound $\left.\begin{matrix}(C^7H^5)'''\\(C^2H^3O)^3\end{matrix}\right\}O^3$, analogous to the ethylic ether just mentioned, or as a compound of acetic and acetobenzoic anhydride, $\left.\begin{matrix}C^2H^3O\\C^7H^5O\end{matrix}\right\}O . \left.\begin{matrix}C^2H^3O\\C^2H^3O\end{matrix}\right\}O$. This body decomposes easily, apparently with separation of acetic anhydride, and leaves a crystalline compound, which has the composition of acetobenzoic anhydride, $\left.\begin{matrix}C^2H^3O\\C^7H^5O\end{matrix}\right\}O$, and separates, after a while, into acetic and benzoic anhydrides. (Limpricht.)

With *aniline*, benzotrichloride forms a base, $C^{19}H^{16}N^2 = \left.\begin{matrix}(C^7H^5)'''\\(C^6H^5)^2\\H\end{matrix}\right\}N^2$, which yields crystallisable salts. (Limpricht.)

TETRACHLOROTOLUENE, $C^7H^4Cl^4$, and its isomers.—A body having this composition, and probably consisting of trichlorobenzylic chloride, $C^6H^2Cl^3.CH^2Cl$, is found among the products of the action of chlorine on toluene. It forms needles, melting at 96°, and boils without decomposition at 276°. It is not decomposed by heating with water to 230°. (Limpricht.)

Chlorobenzoic trichloride, $C^6H^2ClH^2.CCl^3$, the analogue of the true chlorobenzoic acid, is produced (together with benzotrichloride) by the action of phosphoric pentachloride on chloride of benzoyl. It is a liquid, boiling at 250°, not solidifying at 0°, and converted into chlorobenzoic acid by heating with water (Limpricht). Identical with this is the tetrachloride, which was found by Kämmerer and Carins (Ann. Ch. Pharm. cxxx. 158) among the products of the action of phosphoric pentachloride on chloride of benzoyl; also that which Cahours obtained (*ibid.* Suppl. ii. 251) by the action of chlorine on chlorobenzol. Kolbe and Lautemann (*ibid.* cxv. 195), by distilling salicylic acid with pentachloride of phosphorus, obtained a tetrachloride isomeric with the preceding, and perhaps consisting of $C^6H^3ClH.CCl^3$. It melted at 30°, and, when heated with water to 150°, was converted into chlorosalylic acid, isomeric with chlorobenzoic acid. (See p. 185.)

PENTACHLOROTOLUENE, $C^7H^3Cl^5$.—A body having this composition is said by Limpricht to be obtained, together with previously described products, by the action of phosphoric pentachloride on chloride of benzoyl.

HEXCHLOROTOLUENE, $C^7H^2Cl^6$.—A body of this composition was obtained by Deville (Ann. Ch. Pharm. xliv. 304) as the final product of the action of chlorine on toluene (from tolu-balsam). A body of the same composition, and perhaps identical therewith, was obtained by Cahours, by treating chlorobenzol with chlorine. It forms silky needles, which sublime without decomposition, and may be recrystallised from ether.

Respecting the dihydrochlorate and trihydrochlorate of pentachlorotoluene, obtained by Deville, see i. 574.

Ethyltoluene, $C^9H^{12} = C^7H^7(C^2H^5) = C^6H^4(C^2H^5).CH^3$. (Glinzer and Fittig, Ann. Ch. Pharm. cxxxvi. 303; Jahresb. 1865, p. 537.)—This compound, homologous with ethylbenzene or phenyl-ethyl (iv. 484), is produced by the action of sodium on a mixture of bromotoluene and ethylic bromide. It has a peculiar odour, like that of methyltoluene (*infra*), boils at 159°—160°, and has a specific gravity of 0·8652 at 21°. From the isomeric body cumene (obtained from cuminic acid or from coal-tar), it is distinguished by its boiling-point (cumene boiling at 144°—148°), and from mesitylene, with which it is likewise isomeric, by its behaviour with reagents.—Cold fuming *nitric acid* converts it into an oily, non-distillable nitro-compound, probably $C^9H^{10}(NO^2)^2$.—With warm *nitric acid*, it forms trinitro-ethyltoluene, $C^9H^9(NO^2)^3$, which separates in large apparently rhombohedral crystals, melting at 92°.—*Chromic acid* oxidises it to terephthalic acid.

Hydroxyltoluene. Cresol. Cresylic Alcohol. $C^7H^8O = C^6H^4(OH).CH^3$.—This compound, isomeric with benzylic alcohol, $C^6H^5.CH^2(OH)$, and related to toluene in the same manner as phenol to benzene, has already been described, under the last-mentioned name (ii. 106), as a colourless, strongly refracting liquid, obtained from coal-tar and the tar of fir-wood. It is, however, produced in a state of greater purity from toluidine—namely, by treating nitrate of toluidine with nitrous acid, converting the resulting nitrate of diazotoluene into sulphate, and decomposing this compound by boiling with water (p. 867). As thus prepared, it is solid and crystalline.

The nitrocresols are described under CRESYLIC ALCOHOL (ii. 106). Amidodinitrocresol, $C^7H^5(NO^2)^2(NH^2)$, is produced by saturating an alcoholic solution of trinitrocresol, first with ammonia, then with sulphydric acid gas. The deep red liquid is evaporated to dryness, the residue exhausted with ammoniacal water, and the filtered solution acidulated with very dilute sulphuric acid, whereby the amidodinitrocresol is thrown down as a very dark-coloured precipitate, which may be purified by repeated crystallisation from hot water or hot alcohol. It then forms yellow needles, which dissolve but sparingly in hot water, are nearly insoluble in cold water, but dissolve easily in alcohol and in ether. The salts of amidodinitrocresol are, for the most part, but slightly soluble.—The *magnesium-salt* is the most characteristic; it separates, on mixing concentrated solutions of the ammonium-salt and magnesium-sulphate, in small crystals, the solution of which in warm water yields the salt in needles an inch long. (Kellner and Beilstein, Ann. Ch. Pharm. cxxviii. 164.)

Methyltoluene, $C^8H^{10} = C^7H^7(CH^3) = C^6H^4(CH^3).CH^3$. (Glinzer and Fittig, *loc. cit.*)—This compound, isomeric with ethylbenzene or phenyl-ethyl (iv. 484), is prepared, similarly to the latter, by the action of sodium on a mixture of bromotoluene, methylic iodide, and ether, perfectly free from water and alcohol, and cooled with ice. It is a colourless mobile liquid, having a peculiar odour, not like that of benzene, a specific gravity of 0·8621 at 195°, and boiling at 139°—140° (six or seven degrees higher than ethylbenzene). It is probably identical with xylene from coal-tar oil, and forms with fuming sulphuric acid a sulpho-acid, whose barium-salt crystallises, like the xylene-sulphite, in spherical aggregations; the potassium-salt, $C^8H^9KSO^3$, forms silky laminæ.

By oxidation with *chromic acid*, methyltoluene (like xylene) yields terephthalic acid, $C^8H^6O^4$, whereas ethylbenzene yields benzoic acid.

Methyltoluene, warmed with fuming *nitric acid*, forms two isomeric dinitro-compounds, $C^8H^8(NO^2)^2$, one of which melts at 123·5°, and crystallises in long capillary needles; while the other, which melts at 93° (like dinitroxylene), forms large, colourless, monoclinic crystals. When methyltoluene is dropt into a mixture of 2 vols. nitric and 1 vol. fuming sulphuric acid, cooled at the commencement, trinitromethyltoluene, $C^8H^7(NO^2)^3$, is formed as a white precipitate, which separates from alcohol in rather large stellate crystals, melting at 137°.

Dioxymethyltoluene, $C^9H^{12}O^2 = C^7H^6(CH^3O)^2$.—Already described as methylate of benzylene (i. 577). When heated with acetic acid, it is converted into benzoic hydride and methylic acetate:

$$C^7H^6(CH^3O)^2 + 2(C^2H^3O.HO) = C^7H^6O + 2(C^2H^3O.CH^3O) + H^2O.$$

Hydrochloric acid likewise converts it into benzoic hydride. (Cannizzaro, Bull. Soc. Chim. [1866], ii. 216.)

Nitrotoluenes (i. 574).—*Mononitrotoluene*, $C^7H^7(NO^2)$, is there described as a liquid;

but, according to **Jaworsky** (Jahresb. 1865, p. 542), a purer product may be obtained by dissolving ordinary nitrotoluene in fuming sulphuric acid, and treating the product with water, whereupon nitrotoluene-sulphuric acid (p. 860) remains dissolved, and pure nitrotoluene is precipitated; also by redistilling the ordinary product of the action of nitric acid upon toluene, and collecting the portion which distils below 240°. It separates from alcohol, in white shining crystals, which melt at 54°, and distil without decomposition at 238°.

Chloronitrotoluene, $C^6H^3(NO^2)Cl.CH^3$, is formed by the action of fuming nitric acid upon chlorotoluene. The isomeric compound *nitrobenzylic chloride*, $C^6H^4(NO^2).CH^2Cl$, is formed in like manner from benzylic chloride. It crystallises from alcohol in fine colourless laminæ. Chromic acid converts it into nitrodracylic acid.

Benzylic chloride, treated with fuming nitric acid, likewise yields an oily liquid, slightly soluble in alcohol, which has not been much examined. This liquid, treated with chromic acid, also yields nitrodracylic acid. (**Beilstein** and **Geitner**, Bull. Soc. Chim. [1866], ii. 469.)

Trinitrotoluene, $C^7H^5(NO^2)^3$, is obtained by keeping toluene in a state of gentle ebullition with fuming nitric acid for several days, and precipitating with water. It forms white needles, which melt at 82°, are very slightly soluble in cold, easily soluble in boiling alcohol and in ether. It is isomeric with chrysanisic acid. (**Wilbrand**, Ann. Ch. Pharm. cxxviii. 178.)

Oxytolic Acid, $C^7H^6O^3$.—An acid isomeric with oxybenzoic and salicylic acids, produced by oxidising toluene with dilute nitric acid (iv. 321).

Sulphur-derivatives of Toluene, and Compounds isomeric with them.

Märcker (Ann. Ch. Pharm. cxxxvi. 79; Jahresb. 1865, p. 543) has obtained a toluenic sulphydrate analogous to cresol, and the isomeric compound, benzylic sulphydrate, analogous to benzylic alcohol; also toluenic disulphide, and the corresponding benzylic disulphide; and benzylic protosulphide, to which no corresponding toluene-compound has yet been produced.

Benzylic Sulphydrate, $C^7H^8S = \left.\begin{matrix}C^7H^7\\H\end{matrix}\right\}S = C^6H^5.CH^2(SH)$, is obtained by mixing an alcoholic solution of potassic sulphydrate (or sulphocarbonate) with chlorotoluene or bromotoluene (? benzylic chloride or bromide), adding water after 24 hours, and rectifying the oil thereby precipitated (**Märcker**, Ann. Ch. Pharm. cxxxvi. 75; Jahresb. 1865, p. 543). It is a colourless strongly refractive liquid, having a disagreeable alliaceous odour, and makes the eyes water. It has a specific gravity of 1·058 at 20°, and boils at 194°—195°. It decomposes *mercuric oxide*, forming the compound $C^{14}H^{14}Hg''S^2$, which crystallises from hot absolute alcohol in long needles.—With *mercuric chloride*, in alcoholic solution, it forms a precipitate containing $C^{14}H^{14}Hg''S^2.Hg''Cl^2$.—With *acetate of lead*, in alcoholic solution, it forms a crystalline precipitate of plumbobenzylic sulphydrate, $C^{14}H^{14}Pb''S$; with *silver-* and *cadmium-salts*, white precipitates; with *nickel-* and *copper-salts*, green precipitates; and with *iron-*, *cobalt-*, *platinum-*, and *gold-salts*, brown precipitates. Benzylic sulphydrate is converted, by exposure to the air, into benzylic sulphide (p. 859).

Toluenic or *Metabenzylic Sulphydrate*, $C^6H^4(SH).CH^3$. (**Märcker**, *loc. cit.*—**Jaworsky**, Jahresb. 1865, p. 542.)—This compound, isomeric with the preceding, is prepared by distilling toluene-sulphochloride, $C^7H^7SO^2Cl$ (p. 859), with zinc and dilute sulphuric acid. It then passes over with the vapour of water, while the less volatile toluenic sulphide remains behind. It crystallises very easily from ether, in large white laminæ, unctuous to the touch, and having a peculiar odour. It is very soluble in *ether*, sparingly soluble in *alcohol*, insoluble in *water*; melts at 42·5° to 43°, volatilises easily with vapour of water, and distils by itself without decomposition. The alcoholic solution becomes heated in contact with *mercuric oxide*, and forms the compound $C^{14}H^{14}Hg''S^2$, which crystallises in laminæ having a satiny lustre; with *mercuric chloride*, it forms the compound $C^{14}H^{14}Hg''S^2.Hg''Cl^2$.—*Lead-salts* throw down the compound $C^{14}H^{14}Pb''S^2$, in orange-yellow flocks.—*Silver-salts* form a siskin-green, *platinic chloride* an orange-yellow, *auric chloride* a light-green, *nickel-salts* a green, *copper-salts* a green, and *chloride of cobalt* a violet precipitate. Toluylenic sulphydrate dissolves in warm concentrated sulphuric acid, with evolution of sulphurous anhydride, forming a deep-blue solution, from which water throws down a reddish resinous body, redissolved with blue colour by sulphuric acid. Benzylic sulphydrate does not exhibit this reaction. (**Märcker**.)

Benzylic sulphydrate is oxidised by strong nitric acid, forming sulphuric acid, benzoic hydride, and small quantities of other products. Toluylenic sulphydrate, on the other hand, when added to nitric acid of specific gravity 1·3, is converted into toluylenic dioxysulphide, $C^{14}H^{4}O^{2}S^{2}$, while nitrotoluene-sulphuric acid remains in solution, (Märcker.)

Benzylic Sulphide, $(C^7H^7)^2S = \left.\begin{matrix}C^6H^5.CH^2\\ C^6H^5.CH^2\end{matrix}\right\}S$. (Märcker, *loc. cit.*).—This compound is produced by the action of an alcoholic solution of potassic monosulphide on chlorotoluene (more probably tolylic or benzylic chloride), and separates, on dilution with water, as an oily mass, which soon solidifies. It is insoluble in *water*, but dissolves easily in *alcohol* and *ether*, and crystallises, by slow evaporation of its solutions, in long needles by rapid cooling, in shining laminæ. It melts at 49°, volatilises without decomposition, and is not precipitated by metallic salts. When added to cooled *nitric acid* of specific gravity 1·3, it is converted into oily oxybenzylic sulphide, $(C^7H^7)^2SO$, which becomes crystalline on being mixed with water. Benzylic sulphide boiled with *nitric acid* of specific gravity 1·3, or treated with stronger acid, dissolves almost completely, with formation af sulphuric, benzoic, and nitrobenzoic acids, and a small quantity of a yellow acid, the barium-salt of which crystallises in yellow laminæ.

Benzylic sulphide, subjected to dry distillation, gives off a large quantity of sulphydric acid gas, and yields (at 200°) a distillate, consisting of toluene (boiling at 112°) and benzylic sulphydrate. Between 240° and 250°, tolylene, C^7H^6, passes over, solidifying in the crystalline form as it cools; and at still higher temperatures, the distillation being ultimately conducted in a current of air, two other crystalline bodies collect in the neck of the retort—viz., tolallylic sulphide, $(C^7H^5)^2S$ (p. 851), and a body consisting of $C^{28}H^{18}S$, which is insoluble in water, very sparingly soluble in absolute alcohol even at the boiling heat, more soluble in ether or benzene, and crystallises in long white needles; it melts at 180°, sublimes in needles or laminæ, and is, perhaps, identical with Laurent's thionessal (p. 779).

Benzylic Oxysulphide, $(C^7H^7)^2OS$, formed by the action of cooled nitric acid on benzylic sulphide, crystallises from hot water, or from alcohol, in laminæ having a satiny lustre, melts at 130°, and solidifies again at the same temperature. It dissolves readily also in ether, and melts under boiling water before dissolving. (Märcker.)

Benzylic Disulphide, $C^{14}H^{14}S^2 = \left.\begin{matrix}C^6H^5.CH^2\\ C^6H^5.CH^2\end{matrix}\right\}S^2$, is formed, as above mentioned, by the oxidation of benzylic sulphydrate in contact with the air, more quickly on evaporating a solution of the sulphydrate containing ammonia, or by the action of potassium-disulphide on chlorotoluene (benzylic chloride), in alcoholic solution. It crystallises in white shining laminæ, melts at 65° or 67°, dissolves easily in ether and in boiling alcohol, but not in water. It decomposes when heated, yielding the same compounds as the monosulphide, and is reconverted by nascent hydrogen into benzylic sulphydrate. It does not precipitate metallic salts. (Märcker.)

Toluenic or *Metabenzylic Disulphide,* $\left.\begin{matrix}C^6H^4(CH^3)\\ C^6H^4(CH^3)\end{matrix}\right\}S^2$, isomeric with the preceding, remains in the residue obtained in preparing toluenic sulphydrate from toluene-sulphochloride, and is likewise formed, on evaporating a solution of toluenic sulphydrate in alcoholic ammonia. It crystallises in large needles or laminæ, melts at 41°, is insoluble in water, but dissolves easily in hot alcohol, and especially in ether. By hydrogen it is reconverted into toluenic sulphydrate. (Märcker.)

Benzylic Dioxysulphide, $C^{14}H^{14}O^2S^2$, produced by the action of nitric acid on toluenic sulphydrate (p. 858), is insoluble in water and in aqueous potash, but dissolves in ether, alcohol, or benzene, and crystallises in large transparent prisms, which melt at 74°, solidify again at the same temperature, and when quickly heated, burn with brilliant scintillation. The alcoholic solution of this compound is not precipitated by mercuric chloride. (Märcker.)

TOLUENE-SULPHAMIDE. $C^7H^7.SO^2.NH^2$. Syn. with SULPHOTOLUOLAMIDE (p. 527).—Produced by the action of aqueous ammonia on toluene-sulphochloride or toluene-sulphobromide.

TOLUENE-SULPHOBROMIDE. $C^7H^7SO^2Br$. (Otto, Zeitschr. f. Chem. 1866, p. 657.—Otto and v. Gruber, *ibid.* 1867, p. 222.)—Produced by the action of bromine on toluene-sulphurous acid (p. 860) suspended in water. It forms long, oblique, rhombic prisms, insoluble in water, easily soluble in ether and in benzene, and melting at 95°—96°. By warm absolute alcohol, it is converted into ethylic toluene-sulphate; by potash into potassic toluene-sulphate; by ammonia into toluene-sulphamide.

TOLUENE-SULPHOCHLORIDE. $C^7H^7SO^2Cl$. (Fittig, Ann. Ch. Pharm. cvi. 280.—Märcker, *ibid.* cxxxvi. 79.—Jaworsky, Zeitschr. f. Chem. 1865, p. 221. —Otto, *ibid.* 1866, p. 657.)—Obtained by triturating toluene-sulphate of sodium with an equal weight of phosphoric pentachloride, and repeatedly washing the product with water. It is insoluble in water, but dissolves in alcohol, ether, and benzene, and separates from ether in beautiful rhombic plates, or sometimes in large prisms. It melts at 68°—69°, and boils, with almost complete decomposition, at 250°.

It is scarcely attacked by water in the cold, but is slowly decomposed on boiling, and quickly when heated with it in a sealed tube to a temperature above 100°, yielding hydrochloric and toluene-sulphuric acids. The same decomposition is produced by prolonged boiling with alkalis in aqueous solution, rapidly in alcoholic solution. The chloride acts gradually upon alcohol, even in the cold, forming ethyltoluene-sulphate. With aqueous ammonia and solid ammonium-carbonate, it easily forms toluene-sulphamide. When a solution of toluene-sulphochloride in pure and dry ether is treated with sodium-amalgam, toluene-sulphurous acid is produced. The chloride, treated with zinc and dilute sulphuric acid, yields toluene-sulphydrate.

Toluene-sulphochloride dissolves without alteration in a mixture of nitric and sulphuric acids, and is not attacked by strong nitric acid, even at the boiling heat. When distilled, it gives off sulphurous anhydride, and yields a liquid distillate, probably consisting of monochlorotoluene.

TOLUENE-SULPHURIC, TOLUOL-SULPHURIC, or **SULPHOTOLUIC ACID.** $C^7H^8SO^3 = C^7H^7.SO^3H = C^6H^4\left\{\begin{matrix}CH^3\\SO^3H\end{matrix}\right.$ (Deville, Ann. Ch. Pharm. xliv. 306.—Church, Jahresb. 1855, p. 634.—Fittig and Tollens, Ann. Ch. Pharm. cxxxi. 310.—Märcker, *ibid.* cxxxvi. 85.—Jaworsky, Zeitschr. f. Chem. 1865, p. 220.—Otto, *ibid.* 1866, p. 656.)—This acid, already partly described as BENZYLSULPHUROUS ACID (p. 553), was discovered by Deville, who obtained it by the action of fuming sulphuric acid on toluene from tolu-balsam. It was afterwards prepared in like manner by Church, though in an impure state, from the toluene of coal-tar; and by Fittig and Tollens from synthetically-formed methylbenzene or phenyl-methyl (iv. 486). Otto obtained it by oxidation of toluene-sulphurous acid, and Märcker produced it, together with nitrotoluene-sulphuric acid, by treating toluene-sulphydrate with nitric acid. A few of its salts have been examined by Jaworsky.

The *barium-salt*, $C^{14}H^{14}Ba''S^2O^6$, obtained by dissolving toluene in fuming sulphuric acid, neutralising with water after a few days, and saturating with carbonate of barium, forms crystals, permanent in the air, easily soluble in water and in alcohol.—The *lead-salt*, $C^{14}H^{14}Pb''S^2O^6$, usually forms nodular crystalline masses, but may be obtained, by slow evaporation, in needle-shaped crystals; it is easily soluble in water and in alcohol.

Ethylic toluene-sulphate, $C^7H^7.SO^3(C^2H^5)$, is easily produced by the action of toluene-sulphochloride or toluene-sulphobromide on alcohol. It is insoluble in water, but soluble in alcohol and ether, and crystallises in fine thick prisms, which melt at 32°.

Amidotoluene-sulphuric Acid, $C^7H^6(NH^2).SO^3H$. Syn. with SULPHOTOLYLAMIC or BENZYLSULPHAMIC ACID. (See SULPHUROUS ETHERS, p. 527.)

Nitrotoluene-sulphuric Acid, $C^7H^6(NO^2).SO^3H = C^6H^4(NO^2)\left\{\begin{matrix}CH^3\\SO^3H\end{matrix}\right.$—There appear to be two modifications of this acid, the one produced from nitrotoluene by the action of fuming sulphuric acid, the other by that of nitric acid on toluene-sulphydrate, being evidently formed by the nitration of toluene-sulphuric acid. But the two acids have not been sufficiently examined to render their separate existence a matter of certainty.

Nitrotoluene-sulphuric acid is produced by treating toluene-sulphydrate with nitric acid, of specific gravity 1·3, and remains in solution, while toluene-disulphide crystallises out (p. 859). By evaporating the solution, it is obtained in deliquescent crystals.—Its *barium-salt*, $[C^7H^6(NO^2)SO^3]^2Ba''.2H^2O$, forms colourless, transparent, four-sided tablets, which dissolve easily in hot, slightly in cold water, are insoluble in alcohol, and give off their water of crystallisation at 110°.—The *lead-salt*, $[C^7H^6(NO^2)SO^3]^2Pb''.4H^2O$, forms transparent, very bulky, crystalline laminæ. (Märcker.)

Paranitrotoluene-sulphuric acid is produced by gently heating nitrotoluene with fuming sulphuric acid. Its barium-salt forms shining pale-yellow crystals, which contain $[C^7H^6(NO^2)SO^3]^2Ba''.3H^2O$, and give off their water at 110°. (Church; Jaworsky.)

TOLUENE-SULPHUROUS ACID. $C^7H^7.SO^2H = C^6H^4\left\{\begin{matrix}CH^3\\SO^2H\end{matrix}\right.$— *Tolylsulphurous* or *Benzylsulphurous Hydride*. (Otto, Zeitschr. f. Chem. 1866, p. 655.)—This acid is obtained, similarly to the homologous compound benzene-sulphurous acid or phenylsulphurous hydride (p. 564), by treating toluene-sulphochloride, dissolved in ether free from water and alcohol, with sodium-amalgam, and decomposing the resulting sodium-salt with hydrochloric acid. [At the same time there is formed a secondary product, having the empirical formula $C^9H^{10}SO^2$, which dissolves in hot alcohol, and crystallises therefrom in oblique rhombic prisms, melting at 75°—76°.]

Toluene-sulphurous acid crystallises from water in rhombic tables, unctuous to the touch, and having a brilliant satiny lustre; or from dilute solutions in long needles united in large tufts. It melts at 85°, dissolves sparingly in cold water, easily in boiling water—also in alcohol, ether, and benzene.

It is easily converted by oxidation into toluene-sulphuric acid, this effect being produed even by the oxygen of the air, though not so quickly as with benzene-sulphurous acid. When immersed in water, and subjected to the action of chlorine (best at a moderate heat), it is converted into toluene-sulphochloride, hydrochloric acid being formed at the same time. With bromine, in like manner, it yields hydrochloric acid and toluene-sulphobromide.

Toluene-sulphites.—The *barium-salt*, $(C^7H^7SO^2)^2Ba''$, is anhydrous, and crystallises in small shining laminæ, slightly soluble in cold water, more soluble in hot water and in ether.—The *calcium-salt*, $(C^7H^7SO^2)^2Ca''.8H^2O$, resembles the barium-salt in form and solubility.—The *silver-salt*, $C^7H^7SO^2Ag$, forms anhydrous iridescent laminæ, somewhat soluble in boiling water.

Ethylic toluene-sulphite, $C^7H^7.SO^2(C^2H^5)$, is easily produced by heating the acid with alcohol containing hydrochloric acid. It is liquid, insoluble in water, easily soluble in alcohol and ether.

TOLUENYL. Syn. with Tolyl or Benzyl.

TOLU-EUGENYL. Syn. with Eugeno-toluic Anhydride (ii. 605).

TOLUGLYCIC ACID. Syn. with Toluric Acid.

TOLUIC ACID. $C^8H^8O^2 = \left.\begin{matrix}C^8H^7O\\H\end{matrix}\right\}O = C^6H^5.CH^2.CO^2H$ (Kekulé).

Toluolic Acid. Toluylic Acid. (Noad [1847], Phil. Mag. [3], xxxii. 19.—Kraut, *Dissertation über Cuminol und Cymen* [Göttingen, 1854], p. 20.—Cahours, Ann. Ch. Pharm. cviii. 315.—Cannizzaro, *ibid.* xcvi. 246; cxix. 253; cxxiv. 252; Jahresb. 1861, p. 421; 1862, p. 267.—Möller and Strecker, Ann. Ch. Pharm. ciii. 64.—Temple, *ibid.* cxv. 277.—Griess, *ibid.* cxvii. 61.—Beilstein and Yssel de Schepper, *ibid.* cxxxvii. 301; Bull. Soc. Chim. 1866, i. 286.—Kekulé, *ibid.* 1866, ii. 46.)—An aromatic acid, homologous with benzoic acid, and isomeric with anisylous acid and methylic benzoate. It is produced: 1. By the action of dilute nitric acid on cymene (Noad), or xylene (Beilstein):

$$\underset{\text{Cymene.}}{C^{10}H^{14}} + O^6 = \underset{\substack{\text{Toluic}\\\text{acid.}}}{C^8H^8O^2} + \underset{\substack{\text{Oxalic}\\\text{acid.}}}{C^2H^2O^4} + 2H^2O.$$

$$\underset{\text{Xylene.}}{C^8H^{10}} + O^3 = \underset{\substack{\text{Toluic}\\\text{acid.}}}{C^8H^8O^2} + H^2O.$$

2. Synthetically by the action of sodium and carbonic anhydride on bromotoluene (Kekulé):

$$\underset{\substack{\text{Bromoto-}\\\text{luene.}}}{C^7H^7Br} + Na^2 + CO^2 = NaBr + \underset{\substack{\text{Toluate of so-}\\\text{dium.}}}{C^7H^7.CO^2Na}.$$

The toluic acid obtained by either of these three processes exhibits exactly the same properties, and is the true homologue of benzoic acid. A modification, called alpha-toluic acid, differing from toluic acid in some of its properties, but agreeing with it in composition, and in the essential character of being resolved by heat into toluene and carbonic anhydride, ($C^8H^8O^2 = C^7H^8 + CO^2$), is produced by boiling vulpic acid or cyanide of benzyl with alkalis (Cannizzaro). Another modification, obtained by Griess, by the action of nitrous acid on an alcoholic solution of amidotoluic or oxytoluamic acid (iv. 321), has been regarded as homologous with salylic acid; but as this acid has lately been shown to be identical with benzoic acid (p. 185), it is probable that the toluic acid obtained by the last-mentioned process is likewise identical with ordinary toluic acid.

Preparation of Toluic Acid.—1. From cymene.—One pt. of cymene is distilled in a capacious retort with 4 pts. of a mixture of common nitric acid with six times its volume of water, the distillate being repeatedly poured back into the retort. The reaction takes place quietly, the oil first becoming blue, then dark-yellow, then viscid, and finally sinking to the bottom. The operation is finished when the drops of oil, which at first float upon the distillate, are replaced by white crystals, and on cooling the retort becomes filled with these crystals (Noad). If this method (which requires continuous boiling for a week) is exactly followed, and the toluic acid, as it is formed, is removed, so as to prevent any further action of the nitric acid, the acid is obtained perfectly pure (Kraut).—The toluic acid is the purer the weaker the nitric acid, and the more slowly the distillation is conducted; stronger acid acts violently, and forms nitrotoluic acid, which is difficult to separate. In order to effect the separation, the mixture is first freed from nitric acid and a yellow resin, by boiling with milk of lime; the filtered solution of the calcium-salt is then precipitated by hydrochloric or nitric acid; the precipitated acids are dissolved in baryta-water, and evaporated on a water-bath; the residue is treated with water; the solution filtered from the nitrotoluate of barium, which is difficultly soluble, is next evaporated, again treated with cold water, and filtered; and this treatment is repeated till no more nitrotoluate of barium separates out; the liquid is then precipitated by an acid, and the product is recrystallised. (Noad.)

2. From xylene.—The hydrocarbon is oxidised, as in the preceding process, with nitric acid diluted with five or six times its bulk of water, and the product is freed from the small quantity of nitrotoluic acid, formed at the same time, by distillation and treatment with sulphide of ammonium. (Beilstein and De Schepper.)

3. From toluene.—Bromotoluene, mixed with toluene, is introduced into a long-necked flask, provided with an upright condensing-tube; sodium, in quantity rather greater than that required by theory, is added in small pieces; the whole is heated in a water-bath; and a stream of carbonic anhydride is passed into the vessel for 24 to 48 hours. The sodium soon becomes covered with a blue crust, and is converted into a pasty mass of the same colour. As soon as the reaction is finished, the product is treated with water; the solution is filtered, to separate oily matters, consisting of unaltered toluene and bromotoluene, together with secondary products; and the filtered solution of sodium-toluate is acidulated with hydrochloric acid, to precipitate the toluic acid. (Kekulé.)

Properties.—Toluic acid is precipitated from the solutions of its alkaline salts by acids, as a white curdy mass, which appears crystalline under the microscope. It is very soluble in boiling water, and crystallises therefrom in needles on cooling. It dissolves very readily also in alcohol and ether. When pure, it is tasteless and inodorous. It melts at a temperature above 100° (at 175° to 175·5°, according to Kekulé), and sublimes, without decomposition, in fine needles.

Decompositions.—Toluic acid, heated with *lime* or *baryta*, is resolved into toluene and carbonic anhydride: $C^8H^8O^2 = C^7H^8 + CO^2$.—When boiled for some time with strong *nitric acid*, it is converted into nitrotoluic acid.—By distillation with *pentachloride of phosphorus*, it yields toluic chloride, C^8H^7OCl (Cahours).—When introduced into the animal organism, it passes into the urine as toluric acid (p. 868).

A mixture of toluate and formate of calcium yields by distillation, toluic aldehyde, C^8H^8O (Cannizzaro, p. 864):

$$\underset{\substack{\text{Toluate of}\\\text{calcium.}}}{C^{16}H^{14}Ca''O^4} + \underset{\substack{\text{Formate of}\\\text{calcium.}}}{C^2H^2Ca''O^4} = \underset{\substack{\text{Toluylic}\\\text{aldehyde.}}}{2C^8H^8O} + 2Ca''CO^3.$$

Toluates.—Toluic acid is monobasic, and its salts are mostly crystalline; they have not, however, been much examined.—The *ammonium-salt* forms small prisms.—The *barium-salt*, $C^{16}H^{14}Ba''O^4$, obtained by neutralisation, forms confused crystals.—The *calcium-salt*, $C^{16}H^{14}Ca''O^4$, separates from its concentrated aqueous solution in long shining needles.—The *cupric salt*, $C^{16}H^{14}Cu''O^4$, is deposited, on mixing the potassium-salt with cupric sulphate, as a blue precipitate, slightly soluble in water.—The *potassium-salt*, obtained by neutralisation, forms long shining needles.—The *silver-salt*, $C^8H^7AgO^2$, is obtained, by double decomposition, as a curdy precipitate, crystallising from hot water in small needles.—The *sodium-salt* is more soluble than the potassium-salt, and does not crystallise.

Derivatives of Toluic Acid.

IODOTOLUIC ACID, $C^8H^7IO^2$.—Produced by the action of hydriodic acid on diazotolu-oxytoluamic acid (iv. 322). It forms white laminæ or needles, slightly soluble in water, freely in alcohol or ether. (Griess.)

NITROTOLUIC ACID, $C^8H^7(NO^2)O^2$.—This acid is easily produced by boiling toluic acid with strong nitric acid. It may also be prepared directly from cymene, by boiling that hydrocarbon with the strongest fuming nitric acid, as long as red fumes are evolved. The residue deposits a large quantity of crystals on cooling, and gives a considerable precipitate when treated with water; the whole mass is then washed on a filter with cold water, then digested with ammonia and filtered, whereby a little oily matter is separated. The filtrate is decomposed with hydrochloric acid; the precipitated nitrotoluic acid is washed with water, dried, dissolved in hot alcohol, and boiled with animal charcoal; and the filtrate is left to evaporate.

Nitrotoluic acid forms beautiful pale-yellow rhombic prisms, slightly soluble in cold water, soluble in hot alcohol.

Nitrotoluate of Ammonium forms long needles; it easily gives up part of its ammonia, and the whole when boiled with animal charcoal.—The *barium-salt*, $C^{16}H^{12}Ba''(NO^2)^2O^4$, is thrown down, on mixing the ammonium-salt with chloride of barium, as a white curdy precipitate, which dissolves abundantly in hot water, and separates in stellate groups of needles on cooling.—The *calcium-salt*, $C^{16}H^{12}Ca''(NO^2)^2O^4$, is obtained in like manner as a crystalline precipitate, more soluble in water than the barium-salt, and crystallising therefrom in oblique rhombic prisms.—*Cupric salt.* Cupric sulphate forms, with the perfectly neutral ammonium-salt, a precipitate consisting of a basic salt.—The *potassium-salt* is very soluble, and crystallises with difficulty in small needles.—The *silver-salt*, $C^8H^6Ag(NO^2)O^2$, is a white curdy precipitate, very much like chloride of silver, very soluble in boiling water (blackening if too long boiled), from which it separates in feathery crystals on cooling; slightly soluble in alcohol.—The *sodium-salt* is uncrystallisable.—The *strontium-salt* is very much like the barium-salt, excepting that the crystals are larger, and more soluble in water. (Noad.)

Nitrotoluic Ethers.—The *ethylic ether*, $C^8H^6(C^2H^5)(NO^2)O^2$, is prepared by distilling the alcoholic solution of the acid saturated with hydrochloric acid gas, till the mixture of hydrochloric acid and alcohol begins to show turbidity with water; the oil remaining in the retort then solidifies to a crystalline mass, which, after being washed with carbonate of potassium and with water, is dried between blotting-paper. The ether melts in the water-bath, and forms a clear liquid, which, on cooling, solidifies to a radiated crystalline mass. It has a pleasant odour. It is decomposed by potash into alcohol and toluic acid; does not form an amide with ammonia. (Noad.)

Methylic Nitrotoluate, $C^8H^6(CH^3)(NO^2)O^2$, is prepared like the ethyl-compound; but, as it is generally contaminated with black greasy secondary products, it must be dissolved in strong nitric acid, boiled therewith for a short time, and precipitated by water; it then falls down in oily drops, which soon solidify in the crystalline state. It may be completely purified by distillation with water, and is then quite colourless. It dissolves easily in ether, and is resolved by potash into nitrotoluic acid and methylic alcohol. (Noad.)

DINITROTOLUIC ACID, $C^8H^6(NO^2)^2O^2$.—This acid is obtained by digesting nitrotoluic acid, for two days, with a mixture of equal parts of fuming nitric and fuming sulphuric acid; and is precipitated from the solution by water, in crystals, which may be purified by recrystallisation from boiling water.—The *silver-salt*, $C^8H^5Ag(NO^2)^2O^2$, is a white precipitate. (Temple, Ann. Ch. Pharm. cxv. 277.)

OXYTOLUAMIC ACID, $\left.\begin{matrix}H^2\\(C^8H^6O)\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$ or AMIDOTOLUIC ACID, $C^8H^7(NH^2)O^2$, has been already described (iv. 321).

Diazotolu-oxytoluamic Acid, $C^8H^6N^2O^2.C^8H^9NO^2$ (iv. 322).

Appendix to Toluic Acid.

Alphatoluic Acid, $C^8H^8O^2$. (Cannizzaro, Ann. Ch. Pharm. xcvi. 216; further, Compt. rend. lii. 966; liv. 1225; Jahresb. 1861, p. 421; 1862, p. 267.—Möller and Strecker, Ann. Ch. Pharm. cxiii. 64.)—Cannizzaro found, in 1855, that by boiling cyanide of benzyl (i. 573), with potash-ley, an acid is obtained having the composition of toluic acid, but melting below 100°. Möller and Strecker, in 1857, by boiling vulpic acid with baryta-water, also obtained an isomer of toluic acid, which they denominated alphatoluic acid; and Cannizzaro subsequently found that this acid was identical with that which he had obtained from benzylic cyanide.

Preparation.—Benzylic cyanide (i. 573) is boiled with strong potash-ley till the whole is dissolved, and no more ammonia is given off; the liquid is then diluted with water, and the concentrated filtrate precipitated with hydrochloric acid (Cannizzaro).—2. Vulpic acid is boiled for several hours with a solution of barium-hydrate, saturated while warm (potash or soda would produce oxotolylic acid, iv. 217), till the liquid has become colourless; the solution is then filtered, to separate oxalate of barium; and the filtrate is supersaturated with hydrochloric acid, which, as the liquid cools, throws down the greater part of the alphatoluic acid as a crystalline precipitate. The filtered solution, when evaporated, deposits a small additional quantity of the same acid, together with a large quantity of barium-chloride.

Alphatoluic acid, purified by recrystallisation from boiling water, forms broad, thin, colourless, shining laminæ, having the form of acute rhombs, very much like benzoic acid. It has an odour like that of the perspiration of horses. It melts at 76·5°, and gives off (even below 100°), vapours which excite coughing. It boils without decomposition at 265·5° (corrected; the temperature directly observed was 262°). The specific gravity of the solid acid is nearly 1·3; that of the fused acid, compared with water at

[illegible]

Parachlorotoluic Acid. [illegible] in water.

TOLUIC ALDEHYDE. [illegible] With alcoholic potash it forms [illegible]

$$[illegible] = [illegible] + C^8H^{10}O.$$

TOLUIC ANHYDRIDE. [illegible] known.—*Salicylotoluic Anhy*- [illegible] is formed by heating dry salicylate of sodium with [illegible] the product with a mixture of [illegible] the ethereal solution to evaporate [illegible]

TOLUIC CHLORIDE. [illegible] —Formed by distilling toluic acid with [illegible] liquid, of specific gravity [illegible] Fumes in [illegible] with water, alcohol, and [illegible] Heated with salicylic [illegible] it yields [illegible] it yields eugenotoluic anhy- [illegible]

TOLUIC ETHERS. *Ethylic toluate*, [illegible] is obtained by passing [illegible] distilling to about two- [illegible] It is then precipitated as a heavy [illegible] dried over chloride of calcium, [illegible] smelling like benzoic ether, having a [illegible] 228° [illegible]

Ph[illegible] is obtained by distilling salicylotoluic anhydride [illegible] and may be purified by boiling for a short time with weak [illegible] recrystallisation from ether-alcohol. It forms white [illegible] melting at 71° to 72°, and smelling like geraniums when heated. (Kraut.)

TOLUIDENE, or **BENZYLIDENE.** [illegible]—An aldehyde-radicle, related to [illegible] or benzylene (p. 577) in the same manner as ethylidene to ethylene.—The *Bromide*, $C^7H^6Br^2$, is formed by the action of phosphoric pentabromide on bitter-almond-oil, C^7H^6O (p. 853).

By heating toluidine, rosaniline, and other bases with bitter-almond-oil, compounds are obtained, derived from the original compound by substitution of 1 at. toluidene for 2 at. hydrogen.

Benzylidene-rosaniline, $\left.\begin{matrix}(C^6H^6)''\\(C^{20}H^{16})^{vi}\\H\end{matrix}\right\}N^3$, is a copper-coloured, crystalline, feebly basic compound, obtained by heating rosaniline with bitter-almond-oil to 100° or 120° (Schiff, Compt. rend. lxv. 45). The other substitution-products, just mentioned, will be described under TOLUIDINE (p. 867) and TOLYLENE-DIAMINE (p. 872).

TOLUIDES. Compounds homologous with the anilides (iv. 419), derived from toluidine-salts by abstraction of water, or from toluidine by substitution of an acid-radicle for hydrogen, and produced in many instances by heating toluidine with acids; *e.g.*:

$$\underset{\text{Acetic acid.}}{C^2H^3O.H.O} + \underset{\text{Toluidine.}}{C^7H^7.NH^2} - H^2O = \underset{\text{Acetotoluide.}}{C^7H^6(C^2H^3O).NH^2}.$$

They may be regarded as amides containing the radicle tolyl or benzyl; *e.g.*, acetotoluide = tolylacetamide, $\left.\begin{matrix}C^2H^3O\\C^7H^7\\H\end{matrix}\right\}N$. See TOLYLACETAMIDE, TOLYLBENZAMIDE, &c. (pp. 871, 872).

TOLUIDINE. $C^7H^9N^2$ = *Amidotoluene*, $C^7H^7(NH^2)$.—A crystalline base, produced by the reducing action of sulphydric acid or ferrous acetate on nitrotoluene. It has been already described as BENZYLAMINE (i. 575); but Cannizzaro has shown that a base having the same composition but different properties, is formed by the action of alcoholic ammonia on benzylic chloride (p. 867). The compound thus formed is a true ammonia-base or amine, and is properly designated as benzylamine or tolylamine, and represented by the formula $\left.\begin{matrix}C^7H^7\\H^2\end{matrix}\right\}N$; whereas the base obtained by reduction of nitrotoluene is rather to be regarded as amidotoluene or toluidine, $C^7H^7(NH^2)$.

Preparation. (See i. 575).—For preparing toluidine on the large scale, Hugo Müller (Zeitschr. f. Chem. 1864, p. 161; Jahresb. 1864, p. 423) converts commercial toluene, boiling at 108° to 114° (pure toluene boils at 111°), into nitrotoluene, by pouring a mixture of nitric and sulphuric acids into it in a slow stream (if the action becomes too rapid, dinitrotoluene is also formed), and reduces this product with iron and acetic acid. The crystalline toluidine thus obtained is freed from adhering liquid base by drenching it with the portion of American petroleum or Burmese naphtha, which boils between 80° and 100° (chiefly heptylic hydride), and finally recrystallising it from this hydrocarbon. E. Sell (Chem. Soc. J. xvi. 186) prepares toluidine, in considerable quantity, from that portion of the residue of the aniline manufacture (*queues d'aniline*), which boils below 270° (the higher portions containing paraniline, &c., iv. 352). This liquid is distilled in a large copper retort provided with a long condensing-tube not cooled; the portion of the distillate boiling between 180° and 230° is subjected to fractional distillation; the several portions of the distillate are treated with a hot solution of oxalic acid; and the sparingly soluble oxalate of toluidine is decomposed by potash-ley as soon as a sample of the base separated by ammonia solidifies at once. The brown toluidine thus separated, which crystallises on cooling, is washed with water, pressed between paper, and distilled. It passes over between 198° and 200°, and solidifies in the receiver in snow-white crystals, which gradually turn brown in contact with the air. (Sell.)

Toluidine boils at 205°—206°, under a pressure of 730 mm. (Städeler, J. pr. Chem. xcvi. 65.)

Reactions.—Toluidine is absolutely incapable of neutralising dilute sulphuric acid (Wacklyn, *Laboratory*, i. 3). When moderately heated with *fuming sulphuric acid*, it forms tolylsulphamic or sulphotolylamic acid, $C^7H^9NSO^3$ (p. 527; Sell, *loc. cit.*).—An aqueous solution of sulphate of toluidine mixed with *cyanate of potassium*, deposits white needles of monotolylcarbamide, $\left.\begin{matrix}(CO)''\\C^7H^7\\H^3\end{matrix}\right\}N^2$ (Sell). Finely-divided toluidine combines rapidly with *ethylic cyanate*, forming tolyl-ethylcarbamide. $\left.\begin{matrix}(CO)''\\C^7H^7\\C^2H^5\\H^2\end{matrix}\right\}N^2$. (Sell.)

An alcoholic solution of toluidine, heated (not above 80°) with an equal volume of *carbonic disulphide*, forms ditolylsulphocarbamide, $\left.\begin{matrix}(CS)''\\(C^7H^7)^2\\H^2\end{matrix}\right\}N^2$. (Sell.)

Toluidine, fused with an equal weight of *succinic acid*, forms tolylsuccinimide, $\left.\begin{matrix}(C^4H^4O^2)''\\C^7H^7\end{matrix}\right\}N$, and ditolylsuccinamide, $\left.\begin{matrix}(C^4H^4O^2)''\\(C^7H^7)^2\\H^2\end{matrix}\right\}N^2$. (Sell.)

A mixture of toluidine and *acetic acid*, treated with *trichloride of phosphorus*, yields ethenyl-ditoluidine,* $C^{16}H^{18}N^2$ (Hofmann; see p. 867).—With *benzoic hydride* (bitter-almond-oil), toluidine forms dibenzylidene-tolylamine, $C^{14}H^{26}N^2 = N^2(\overset{''}{C^7H^6})^2(C^7H^7)^2$ (Schiff, Jahresb. xviii. 429).—With *quinone* and *perchloroquinone*, toluidine forms compounds homologous with those produced by aniline (Hofmann, iv. 426).—A mixture of 1 at. hydrochlorate of toluidine and 1 at. *azobenzene* is converted (at 230°) into a black mass, containing, together with unaltered toluidine, a ruby-red colouring-matter soluble in hot water, a violet substance somewhat less soluble in water, and a blue substance soluble in alcohol.—With *nitrobenzene*, in like manner, a tarry greenish mass is formed, which does not contain any colouring-matters (Städeler, Jahresb. 1865, p. 409).—Toluidine heated with half its weight of *acetate of rosaniline*, forms tritolyl-rosaniline or toluidine-blue, $C^{20}H^{16}(C^7H^7)^3N^3$. (Hofmann, iv. 472.)

Cyanotoluidine, $C^8H^9N^2$ (i. 576), is resolved, by evaporation of its hydrochlorate, similarly to cyaniline (iv. 443), into sal-ammoniac, hydrochlorate of toluidine, oxamide, monotolyloxamide, and ditolyloxamide. (Sell.)

Derivatives of Toluidine containing Alcohol-radicles.

PHENYLTOLUIDINE, $C^{13}H^{13}N = C^7H^6(C^6H^5).NH^2$.—This base, which Hofmann obtained by the dry distillation of a salt of tritolyl-rosaniline (iv. 472), is likewise produced, together with diphenylamine and ditolylamine, by heating hydrochlorate of toluidine with aniline, or hydrochlorate of aniline with toluidine. The three bases may be separated by fractional distillation, but the separation is difficult, as their boiling-points do not differ by more than 25° or 30°. Phenyltoluidine boils at about 330°. (De Laire, Girard, and Chapoteaut, Bull. Soc. Chim. 1866, *ii. 360.*)

BENZYLTOLUIDINE, or TOLYLTOLUIDINE, $C^{14}H^{15}N = C^7H^6(C^7H^7).NH^2$. *Ditolylamine.*—Produced by heating 1 at. hydrochlorate of toluidine with 1½ at. of the free base, to 210°—240°, in a long-necked flask provided with a condensing-tube, or more quickly by heating the mixture in a sealed tube under a pressure of four or five atmospheres. On treating the product with hydrochloric acid diluted with twenty or thirty times its bulk of water, the hydrochlorate of benzyltoluidine is decomposed by the water; and the benzyltoluidine thus separated, floats on the surface as an oil which solidifies on cooling, and may be purified by recrystallisation. It boils between 355° and 360°. It forms unstable salts, which are decomposed by water. Nitric acid turns it yellow, a character by which it is distinguished from diphenylamine. (De Laire, Girard, and Chapoteaut, *loc. cit.*)

DIBENZYLTOLUIDINE, $C^{21}H^{21}N = C^7H^5(C^7H^7)^2.NH^2$.—This base, isomeric with tribenzylamine, $(C^7H^7)H^3N$ (i. 576), is produced by heating an alcoholic solution of 1 at. toluidine with 2 at. benzylic chloride, and subjecting the base, separated from the product by potash, to a repetition of the same treatment. It crystallises in slender needles, melting between 54·5° and 55° (tribenzylamine crystallises in small tables, and melts at about 93°). It is insoluble in water, slightly soluble in cold, easily in hot alcohol, and becomes yellowish on exposure to light.—The *hydrochlorate* dissolves readily in alcohol, and is decomposed by water, with separation of the base.—The *chloroplatinate*, which is also decomposed by water, crystallises from an alcoholic solution mixed with ether. (Cannizzaro.)

Derivatives of Toluidine containing Aldehyde-radicles.

These compounds are formed by the action of aldehydes on toluidine.—*Diethylidene-ditoluidine*, $C^{18}H^{22}N^2 = C^{14}H^{10}(\overset{''}{C^2H^4})^2.(NH^2)^2 = (\overset{''}{C^2H^4})^2.(C^7H^7)^2N^2$, obtained by the action of acetic aldehyde on toluidine, crystallises in yellow nodules, and forms red resinous salts with acids.—*Diallylidene-ditoluidine*, $(\overset{''}{C^3H^4})^2(C^7H^7)^2N^2$, is obtained in like manner with acrolein, as a brown resinous mass.—*Dibenzylidene-ditoluidine*,

---

* Ethenyl, C^2H^3, is the triatomic radicle commonly called *Vinyl*. For Hofmann's systematic nomenclature of hydrocarbons, see Proc. Roy. Soc. xv. 55.

$C^{28}H^{26}N^2 = (C^7H^6)^2(C^7H^7)^2N^2$, produced by the action of bitter-almond-oil on toluidine, separates from alcohol as a yellow, crystalline, indifferent body, which melts in boiling water, and is converted, at 160°, into yellow needles, melting at 120°—125°, and capable of combining with acids and chlorides. (Schiff, Zeitschr. f. Chem. 1865, p. 400.)

Ethenyl-ditoluidine, $C^{16}H^{18}N^2 = C^{14}H^{11}(C^2H^3)'''.(NH^2)^2$. (Hofmann, Proc. Roy. Soc. xv. 55; Jahresb. 1865, p. 415.)—This base, derived from 2 at. toluidine by substitution of the triatomic radicle ethenyl (vinyl) for 3 at. hydrogen, is produced by the action of trichloride of phosphorus and chloride of acetyl on toluidine at 160°:

$$6C^7H^9N + 3C^2H^3OCl + PCl^3 = 3C^{16}H^{18}N^2 + PH^3O^3 + 6HCl.$$

When purified by recrystallisation from alcohol, it forms white laminæ, resembling the corresponding phenyl-compounds.

Azotoluidines.

Azotoluidine, or Diazotoluene, $C^7H^6N^2 = C^7H^4N'''.NH^2$. (Griess, Chem. Soc. J. xx. 86.)—The salts of this base (which has not been obtained in the free state) exhibit considerable analogy, in their properties and modes of formation, to the corresponding aniline-derivatives (iv. 430); they appear, however, to be somewhat more stable, and to crystallise more readily.

The *nitrate*, $C^7H^6N^2.NHO^3$, is best prepared by the action of nitrous acid on an aqueous solution of nitrate of toluidine, but it may also be formed from azoditoluidine. It forms long white needles, which are decomposed on boiling with water, according to the equation:

$$\underset{\text{Nitrate of Azotoluidine.}}{C^7H^6N^2.NHO^3} + H^2O = \underset{\text{Cresol.}}{C^7H^8O} + NHO^3 + N^2.$$

The other salts are obtained from the nitrate in the same manner as the corresponding phenyl-compounds.—The *chloroplatinate*, $2(C^7H^6N^2.HCl).PtCl^4$, is precipitated, in fine yellow prisms, on adding platinic chloride to a dilute solution of the hydrochlorate. When ignited with soda, it yields an aromatic oil, having the composition of chlorotoluene, C^7H^7Cl.

The *sulphate*, $C^7H^6N^2.SH^2O^4$, is obtained in brilliant plates, needles, or prisms, according to the circumstances under which it crystallises. When heated with strong sulphuric acid, it gives off the whole of its nitrogen, and is converted into disulphotolylenic acid, $C^7H^{10}S^2O^8 = C^7H^6.2SH^2O^4$, the barium-salt of which, $C^7H^6Ba''S^2O^8$, crystallises in long white needles.—The *perbromide*, $C^7H^6N^2.HBr^3$, is precipitated by bromine-water from aqueous nitrate of azotoluidine, as a yellow oil, which, after evaporation of the excess of bromine, solidifies to a crystalline mass.

Azoditoluidine, $C^{14}H^{15}N^3 = C^{14}H^{11}N'''.(NH^2)^2$, or Diazotoluene-amidotoluene, $\left\{\begin{matrix}C^7H^6N^2\\C^7H^7(NH^2)\end{matrix}\right.$.—This base is produced by passing nitrous acid vapour through a solution of toluidine in a small quantity of strong alcohol mixed with two or three times its volume of ether, till a drop of the solution leaves, on evaporation, a residue of yellow needles. The solution of these crystals, left to evaporate, deposits the base in yellow needles, which must be washed with alcohol, and recrystallised from a mixture of alcohol and ether. The crystals have a strong lustre, and correspond, in solubility and other properties, with azodiphenyl-diamine (iv. 459).

The *chloroplatinate*, $C^{14}H^{15}N^3.2HCl.PtCl^4$, is obtained in glittering plates, resembling iodide of lead, on mixing an alcoholic solution of the base with platinic chloride; it deflagrates at a high temperature. (Griess, Chem. Soc. J. xix. 67.)

Azophenyltoluidine, $C^{13}H^{13}N^3 = C^{13}H^9N'''.(NH^2)^2$, or Diazotoluene-amidobenzene, $\left.\begin{matrix}C^7H^6N^2\\C^6H^5(NH^2)\end{matrix}\right\}$, obtained by the action of aniline on nitrate of azotoluidine, crystallises in beautiful long yellow needles. (Griess, Chem. Soc. J. xx. 87.)

Appendix to Toluidine.

Benzylamine, $C^7H^9N = \left.\begin{matrix}C^7H^7\\H\end{matrix}\right\}N$. (Cannizzaro, Bull. Soc. Chim. 1864, ii. 126; 1865, ii. 218.)—This base, isomeric with toluidine, is formed, together with tribenzylamine, $(C^7H^7)^3N$ (i. 574), and probably also with dibenzylamine, $(C^7H^7)^2HN$, by the action of alcoholic ammonia on benzylic chloride, C^7H^7Cl. The mixture, after a few days, deposits tabular crystals of tribenzylamine, and on evaporating the filtered liquid in the water-bath, and treating the residue with hot water, a further portion of tribenzylamine remains undissolved, and the solution contains, together with sal-ammoniac, the hydrochlorate of benzylamine, and probably also of dibenzylamine. The hydrochlorate of benzylamine is separated from the more soluble portion by fractional crystallisation; and the free base separated from this salt by potash is dissolved in ether, freed from ether by evaporation, dehydrated by fused potash out of contact with the air, and then distilled—the portion which gives over at 182° being collected apart. For complete purification, it is converted into the solid carbonate by exposure to a stream of dry carbonic anhydride; the carbonate is washed with anhydrous ether, and dissolved in hydrochloric acid; and the crystallised hydrochlorate is decomposed with potash as above.

Benzylamine, thus prepared, is a colourless liquid, not altered by light, and boiling at 182°—183°. (Toluidine, described, at vol. i. p. 575, as benzylamine, is crystalline at ordinary temperatures, and melts at [illegible]°). It mixes with water in all proportions (toluidine is but slightly soluble in cold water), and is separated therefrom by potash, with faint yellowish colour. It absorbs carbonic anhydride rapidly, forming a crystalline compound; has a strong alkaline reaction; forms white fumes with hydrochloric acid, and unites with acids, producing rise of temperature. Altogether, it appears to be a stronger base than toluidine.—*Hydrochlorate of benzylamine*, $C^7H^9N.HCl$, crystallises in striated tables; the *chloroplatinate* in orange-coloured laminæ.

Dibenzylamine, $(C^7H^7)^2HN$, isomeric with benzyltoluidine, has not been isolated, but appears to be formed, together with mono- and tri-benzylamine, in the process above described.

Tribenzylamine, $(C^7H^7)^3N$, isomeric with dibenzyltoluidine (p. 866), has been already described (i. 574).

Phenyl-benzylamine, $C^{13}H^{13}N = \left.\begin{matrix}C^6H^5\\C^7H^7\\H\end{matrix}\right\}N.$ (Fleischer, Ann. Ch. Pharm. cxxxviii. p. 225; Bull. Soc. Chim. [1866], ii. 235.)—This base, isomeric with Hofmann's tolylaniline (iv. 454), is produced by mixing aniline with benzylic chloride (boiling at 170°).* The mixture becomes hot, and deposits white crystals, consisting of hydrochlorate of aniline, together with phenyl-benzylamine:

$$C^7H^7Cl + 2C^6H^7N = C^6H^7N.HCl + C^{13}H^{13}N.$$

The mixture must be heated to 160° for twenty-four hours, to complete the reaction; and on dissolving out the hydrochlorate of aniline from the product by water, the phenyl-benzylamine remains as an oil, which is converted by hydrochloric acid into crystals of the hydrochlorate, $C^{13}H^{13}N.HCl$. On decomposing this salt with soda, and distilling the liberated base under a pressure of 45 millimetres, the greater part passes over, between 200° and 220°, in the form of an oily liquid, which solidifies at a low temperature, and may be purified by pressure between bibulous paper, and recrystallisation from boiling alcohol.

Phenyl-benzylamine crystallises in colourless four-sided prisms, insoluble in water, but soluble in alcohol and in ether. It melts at 32°, remains in a state of surfusion at 12°, and boils under the ordinary pressure at a temperature above 310°. (Tolylaniline melts at 87°, and boils at 334°).—The *hydrochlorate*, $C^{13}H^{13}N.HCl$, forms colourless crystals.—The *oxalate*, $(C^{13}H^{13}N)^2.C^2H^2O^4$, forms white laminæ.—The base forms, with *chloride of cadmium*, the compound $C^{13}H^{13}N.CdCl^2$.

Phenyl-benzylamine, fused with mercuric chloride, forms at first a green mass, which dissolves in alcohol with fine blue colour; but by the prolonged action of heat, this mass assumes a dark colour, and then forms with alcohol a crimson solution.

Phenyl-benzylamine treated with *chloride of benzoyl* forms phenyl-benzyl-benzamide, $(C^6H^5)(C^7H^7)(C^7H^5O)N$, which crystallises in oblique prisms.

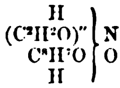
TOLUOL. Syn. with TOLUENE.

TOLUOLIC ACID. Syn. with TOLUIC ACID.

TOLUONITRILE. Syn. with BENZYLCYANIDE (i. 573).

TOLUOSALICYL, or **TOLUOSALICYLOL.** See SALICYLOL (p. 170).

TOLUOXYL. C^8H^7O.—The radicle of toluic acid and its derivatives. (Footnote, p. 869.)



TOLURIC ACID. $C^{10}H^{11}NO^3 = \left.\begin{matrix}H\\(C^2H^2O)''\\C^8H^7O\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$.—*Toluglycic Acid. Glycocol-toluic Acid.* (Kraut, Ann. Ch. Pharm. xcviii. 360.)—An acid homologous with

---

* Chlorotoluene (according to Fleischer), but the boiling-point shows that the compound used was really benzylic chloride (p. 851).

hippuric acid, produced in the passage of toluic acid through the animal body, just as hippuric acid is formed from benzoic acid (iii. 158). To obtain it, toluic acid is swallowed in doses of several grammes (which may be done without injury to the health); the acid urine afterwards voided is evaporated to a syrup; this residue is exhausted with alcohol; the solution is mixed with oxalic acid and left to evaporate; and the residue is finally exhausted with alcoholic ether. The yellowish toluric acid still contaminated with oxalic acid, which remains on evaporating this last solution, is boiled with calcic carbonate; the calcium-salt, which crystallises out on cooling, is purified by repeated crystallisation, and then decomposed by heating it with dilute hydrochloric acid; and the acid, which crystallises out on cooling, is purified by solution in boiling water. It may be obtained in large crystals, by spontaneous evaporation of the alcoholic solution.

Toluric acid crystallises from boiling water in colourless laminæ; from alcohol in trimetric prisms, exhibiting the combination $\infty P \,.\, \infty\bar{P}\infty \,.\, \bar{P}\infty$, also with oP; they are as hard as gypsum, and have a vitreous and nacreous lustre. The acid is inodorous, melts at 160°—165°, and decomposes at a stronger heat, emitting an aromatic odour. It dissolves freely in boiling water, slightly in cold water; in almost any proportion of hot alcohol, abundantly also in cold alcohol, sparingly in ether free from alcohol.

Toluric acid, boiled with hydrochloric acid, is resolved, similarly to hippuric acid, into toluic acid and glycocine:

$$\underset{\text{Toluric acid.}}{C^{10}H^{11}NO^3} + H^2O = \underset{\text{Toluic acid.}}{C^8H^8O^2} + \underset{\text{Glycocine.}}{C^2H^5NO^2}.$$

Tolurates.—Most of these salts are soluble in water, those of the alkali-metals being the most soluble.

The *barium-salt*, $C^{20}H^{20}Ba''N^2O^6.5H^2O$, crystallises in small needles, apparently trimetric, exhibiting the faces ∞P, $\infty P\infty$; it dissolves easily in hot water.—The *calcium-salt*, $C^{20}H^{20}Ca''N^2O^6.3H^2O$, forms flattened crystals, one or two millimetres long, and strongly streaked parallel to their axis; very soft, and having a silky lustre; sparingly soluble in cold, easily in hot water.—The *silver-salt*, $C^{10}H^{10}AgNO^3$, obtained by double decomposition, is very soluble in hot water, and separates in well-defined crystals on cooling.—The *sodium-salt* crystallises from water in feathery needles.

The solution of the sodium-salt forms a white precipitate with neutral acetate of lead, brownish-yellow with ferric chloride. The latter precipitate is soluble in alcohol, and melts partially when boiled with water.

TOLUYL. C^8H^9.—The radicle of toluylic alcohol and its allied compounds;* isomeric with xylyl. Free toluyl, $\left.\begin{matrix}C^8H^9\\C^8H^9\end{matrix}\right\}$, obtained by the action of sodium on toluylic chloride, is a thick liquid, boiling at 296°. (**Vollrath**, Zeitschr. f. Chem. [2], ii. 488; Bull. Soc. Chim. [1867], i. 343.)

TOLUYLAMINE. A name sometimes applied to toluidine.

TOLUYLENE. A name sometimes given to tolylene or benzylene, C^7H^6, but more properly belonging to the hydrocarbon C^8H^8.

TOLUYLIC ACETATE, $C^2H^3(C^8H^9)O^2$, obtained by the action of toluylic chloride on acetate of potassium, or (better) on acetate of silver, is a liquid having an agreeable odour, and boiling at 226°. Alcoholic potash easily converts it into toluylic alcohol.

TOLUYLIC ACID. Syn. with TOLUIC ACID (p. 861).

TOLUYLIC ALCOHOL. $C^8H^{10}O = \left.\begin{matrix}C^8H^9\\H\end{matrix}\right\}O$. *Toluic* or *Toluenylic Alcohol.* (**Cannizzaro**, Compt. rend. liv. 1225; Jahresb. 1862, p. 267.)—An alcohol isomeric with xylylic alcohol, obtained: 1. By the action of alcoholic potash on toluic aldehyde (**Cannizzaro**):

$$\underset{\substack{\text{Toluylic}\\\text{aldehyde.}}}{2C^8H^8O} + KHO = \underset{\substack{\text{Toluate}\\\text{of potas-}\\\text{sium.}}}{C^8H^7KO^2} + \underset{\substack{\text{Toluylic}\\\text{alcohol.}}}{C^8H^{10}O}.$$

2. By the action of alcoholic potash on toluylic acetate (**Vollrath**). It is a white crystalline body, which melts at 58·5°—59·5°, and boils at 217° (xylylic alcohol is an oil, which merely becomes viscid at —18°, and boils at about 220°). Toluylic alcohol is slightly soluble in cold water, somewhat more freely in boiling water, and separates

---

* The name toluyl is also applied, sometimes, to C^8H^7O, the radicle of toluic acid; sometimes to the radicle C^7H^7, more properly called **tolyl**; which latter name, on the other hand, is given by Vollrath to the radicle C^8H^9. To avoid all this confusion, it is advisable to designate C^7H^7 as **tolyl** or **benzyl**, C^8H^9 as **toluyl**, and C^8H^7O as **oxytoluyl** or **toluoxyl**.

therefrom in oily drops, which afterwards solidify in needle-shaped crystals; it is easily soluble in alcohol and in ether. Nitric acid converts it into toluic aldehyde. Heated in a stream of chlorine-gas, it is converted into toluylic chloride, C^8H^9Cl; and this compound, heated with cyanide of potassium in alcoholic solution, is transformed into toluylic cyanide, $C^9H^9N = C^8H^9CN$, which, when distilled with potash, yields alphatoluic acid (p. 864).

TOLUYLIC CHLORIDE, C^8H^9Cl (Vollrath, Zeitschr f. Chem. [2], ii. 488), produced by the action of chlorine on xylene, C^8H^{10}, at the boiling heat, is a liquid having a disagreeable odour, and boiling at 193°. When treated with cyanide of potassium, in presence of alcohol, and then with potash, it yields alphaxylylic acid, $C^9H^{10}O^2 = C^6H^4\left\{\begin{matrix}CH^3\\ CH^2.COHO.\end{matrix}\right.$ (See Xylylic Acid.)

TOLUYLIC SULPHIDE and **SULPHYDRATE.** Both sulphide and sulphydrate of potassium act very strongly on toluylic chloride, producing in the one case the sulphide of toluyl, $(C^8H^9)^2S$, in the other sulphydrate, $C^8H^9.H.S$. Both these compounds are liquids of disagreeable odour. The sulphydrate forms a bulky white precipitate with an alcoholic solution of mercuric chloride, and yellow with acetate of lead. (Vollrath.)

TOLYL, or **BENZYL.** $C^7H^7 = C^6H^4(CH^3)$.—A monatomic radicle, which may be supposed to exist in benzylic alcohol, benzylamine, tolylic or benzylic bromide, chloride, &c. The name *benzyl* is the most convenient for it, as tolyl is too much like toluyl.

Benzyl in the free state, $C^{14}H^{14}$, is obtained by heating benzylic chloride with excess of sodium to 100°, treating the product with ether, and evaporating the ethereal solution. It then remains as an oily body, which crystallises, after some time, in needles and laminæ. When purified by pressure between paper, and repeated crystallisation from strong alcohol, it forms white monoclinic crystals, exhibiting the combination $\infty P\infty \,.\, +P\infty \,.\, -P\infty \,.\, oP \,.\, -\tfrac{1}{3}P\infty$, tabular from predominance of $-P\infty$, and indistinctly cleavable parallel to ∞P and $[\infty P\infty]$. The following angular magnitudes have been approximately determined: $\infty P\infty : +P\infty = 150°$; $[\infty P\infty] : +P = 132°$; $oP : +P\infty = 131\tfrac{1}{2}°$. Benzyl melts between 51·5° and 52·5°, distils without decomposition at 284°, is insoluble in water, but dissolves in alcohol, ether, and sulphide of carbon. (Cannizzaro and Rossi, Ann. Ch. Pharm. cxxi. *250; Jahresb.* 1861, p. 548.)

Benzyl is likewise produced by the action of sodium on bromide of benzylidene, $C^7H^6Br^2$ (p. 853). Sodium acts rapidly on this compound at 180°, hydrobromic acid being given off, and a thick black mass formed, which is partly soluble in ether. On distilling the soluble portion of the product, toluene is given off at 109°; and the black resinous residue, if further distilled in a stream of aqueous vapour, gives off an oily liquid, which soon solidifies to a crystalline mass of benzyl, $C^{14}H^{14}$ (Michaelson and Lippmann, Ann. Ch. Pharm. Suppl. iv. 113; Jahresb. 1865, p. 550). The authors regarded the product thus obtained as isomeric with benzyl, and called it isobenzyl, because it appeared to unite directly with bromine, instead of forming substitution-products, like the benzyl obtained by the process of Cannizzaro and Rossi; but Fittig has shown (Ann. Ch. Pharm. cxxxvii. 271), that benzyl obtained by either process acts in the same manner with bromine.

Several substitution-derivatives of the molecule $C^{14}H^{14}$, called **dibenzyl-compounds**, have been obtained by Stelling and Fittig (Ann. Ch. Pharm. cxxxvii. 257; Jahresb. 1865, p. 547).

Amidobenzyl, or *Diamidodibenzyl*, $C^{14}H^{16}N^2 = C^{14}H^{12}(NH^2)^2$, is produced by reducing nitrobenzyl (p. 871) with tin and strong hydrochloric acid, and is thrown down by ammonia—from the solution previously freed from tin—as an amorphous precipitate. It resembles the homologous compound, amidophenyl or benzidine (iv. 411), and crystallises from hot water in colourless scales, which are nearly insoluble in cold water, very soluble in alcohol, melt at 132°, and sublime, almost without decomposition, at a higher temperature. It is a base, and forms crystalline salts.

The *hydrochlorate*, $C^{14}H^{16}N^2.2HCl$, is very soluble in water and alcohol, and separates from strong hydrochloric acid in small colourless crystals.—The *chloroplatinate*, $C^{14}H^{16}N^2.2HCl.PtCl^4$, forms easily decomposable needles, united in concentric groups. —The *sulphate*, $C^{14}H^{16}N^2.H^2SO^4$, is a white crystalline powder, slightly soluble in water.—The *neutral oxalate*, $C^{14}H^{16}N^2.C^2H^2O^4$, is a crystalline precipitate; the *acid oxalate*, $C^{14}H^{16}N^2.2C^2H^2O^4.3H^2O$, is deposited in hard, transparent, prismatic crystals, nearly insoluble in cold water.—The *phosphate* is a white precipitate.—The *chromate* forms easily decomposable yellow needles.

Isonitrobenzyl is easily reduced by tin and hydrochloric acid to a base, which soon changes to a tarry mass.

Bromobenzyls.—Benzyl, suspended in water and mixed with bromine, yields a pasty mass consisting of several substitution-products. On dissolving the product, decolorised with soda-ley, in hot alcohol, dibromodibenzyl crystallises out first, while the monobrominated compound remains in solution.—*Monobromodibenzyl*, $C^{14}H^{13}Br$, when purified by distillation, is a colourless viscid oil, having a specific gravity of 1·398 at 9°. It solidifies below 0°, in the crystalline form, boils at a temperature above 310°, and, like the following compound, is not decomposed by heating to 140° with alcoholic solution of ammonia, iodide of potassium, or cyanide of potassium.—*Dibromodibenzyl*, $C^{14}H^{12}Br^2$, is nearly insoluble in cold alcohol and benzene, very sparingly soluble in hot alcohol, melts at 114°—115°, and crystallises in colourless prisms or needles.—*Tribromodibenzyl*, $C^{14}H^{11}Br^3$ (or, perhaps, $C^{14}H^{12}Br.Br^2$), is formed, together with dibromodibenzyl, when the quantity of bromine used is sufficient to cause the mass, which is pasty at first, to become solid and friable. It is still less soluble in alcohol than the dibrominated compound, and in the pure state forms nacreous laminæ, which decompose at 170°, without previous fusion.—*Hexbromodibenzyl*, $C^{14}H^8Br^6$, is obtained by bringing dibromodibenzyl in contact with excess of bromine, and recrystallising the product from benzene, in hard, colourless, well-defined prisms, nearly insoluble in alcohol.

Bromide of Benzyl, or *Dibromide of Dibenzyl*, $C^{14}H^{14}Br^2$.—This compound is formed, together with monobromobenzyl, by adding bromine to an ethereal solution of benzyl; and crystallises in colourless silky needles, not fusible without decomposition. It dissolves in boiling alcoholic potash, with formation of monobromodibenzyl. (Michaelson and Lippmann; Fittig.)

Nitrobenzyl, or *Dinitrodibenzyl*, $C^{14}H^{12}(NO^2)^2$.—Fuming nitric acid acts violently on benzyl, even in the cold, converting it into two isomeric nitro-compounds, which may be separated from one another by crystallisation from alcohol. The hot saturated solution first deposits long slender needles of nitrobenzyl, insoluble in water, only slightly soluble in hot alcohol, ether, chloroform, or benzene, and melting at 106°—107°. The mother-liquor, when concentrated, deposits the more soluble *isonitrobenzyl*, partly in crystalline nodules, partly as a thick oil. This compound crystallises from alcohol in extremely fine needles, which form a bulky woolly mass when dry, and melt at 74°—75°. These nitro-compounds are reduced, by tin and hydrochloric acid, to the corresponding amido-compounds (p. 870).

Nitrobromobenzyl, $C^{14}H^{10}(NO^2)^2Br^2$, is produced by dissolving bromobenzyl in warm fuming nitric acid. When purified by washing the crystals which separate on cooling, with hot alcohol, and recrystallising the undissolved powder from benzene, it forms well-developed sword-shaped crystals, which melt at 204°—205°, are nearly insoluble in hot alcohol, more soluble in hot benzene.

TOLYLACETAMIDE, or **BENZYLACETAMIDE**, $C^9H^{11}NO^2 = \left.\begin{matrix}C^7H^7\\C^2H^3O\\H\end{matrix}\right\}N$, or **ACETOTOLUIDE**, $C^7H^6(C^2H^3O).NH^2$. (Riche and Bérard, Ann. Ch. Pharm. cxxix. 77; Jahresb. 1863, p. 428.—Städeler and Arndt, Jahresb. 1864, p. 426.)—This compound, homologous with phenylacetamide (iv. 418), is produced by distilling 1 at. toluidine with 1 at. acetic acid, and remains, on treating the last portion of the distillate with acidulated water, as a white residue melting at 145° (Riche and Bérard). It is likewise formed in the manufacture of aniline by reduction of commercial nitrobenzene with iron and acetic acid. The viscid oils which pass over towards the end of the operation, contain a solid body which, when purified by pressure between paper and repeated crystallisation, exhibits the composition of acetoluide (Riche and Bérard). Städeler and Arndt found the solid mass, obtained by repeated distillation of crude commercial aniline with glacial acetic acid, to consist chiefly of acetanilide and acetoluide. The latter was separated by solution in strong sulphuric or acetic acid, precipitation with water, and crystallisation, or sublimation in a stream of carbonic anhydride.

Acetoluide, when sublimed or quickly crystallised, forms small slender needles like sublimed benzoic acid; by slow crystallisation, it is obtained in longer and thicker brittle needles. It is tasteless, and at ordinary temperatures inodorous, melts at 145°—145·5°, evolving aromatic cough-exciting vapours, and boils at 310°—350°. It is sparingly soluble in cold water (in 1786 pts. 6·5°), easily soluble in boiling water, also in alcohol and ether. It dissolves in concentrated acids, and is precipitated therefrom by water—not decomposed by boiling with dilute acids, or with aqueous alkalis (Städeler and Arndt). According to Riche and Bérard, it is slowly decomposed by boiling with aqueous potash, and quickly by distillation over fused potassium-hydrate, into toluidine and acetic acid; the same decomposition is easily produced by alcoholic potash (Städeler and Arndt). Its solution in strong sulphuric acid acquires a fine green colour on addition of potassic chromate. (Städeler and Arndt.)

TOLYLAMINE. Syn. with Benzylamine (p. 867).

TOLYLANILINE. $C^6H^4(C^7H^7).NH^2$.—A base isomeric, if not identical, with phenyltoluidine (iv. 454; v. 866).

TOLYLBENZAMIDE, BENZYLBENZAMIDE, or **BENZOTOLUIDE,** $C^{14}H^{13}N = C^7H^7.C^7H^5O.HN = C^7H^6(C^7H^5O).NH^2$. (Jaillard, Compt. rend. lx. 1096; Jahresb. 1865, p. 428.)—Prepared by treating chloride of benzoyl with toluidine, washing the resulting hard mass with acidulated water, and dissolving it in boiling alcohol of 90 per cent. It then crystallises, on cooling, in long, colourless, and inodorous needles, insoluble in water, easily soluble in alcohol and in ether. It melts at 100°, and volatilises without decomposition at 232°. When heated with alkalis, it is resolved into benzoic acid and toluidine.

TOLYLCARBAMIDE, BENZYLCARBAMIDE, or **CARBOTOLUIDE.** $C^8H^{10}N^2O = \left.\begin{matrix}(CO)''\\ C^7H^7\\ H^3\end{matrix}\right\}N^2$.—*Benzyl-urea* (Sell, Chem. Soc. J. xvi. 190; Jahresb. 1865, p. 426) separates, on mixing a hot aqueous solution of toluidine-sulphate with a recently prepared solution of potassium-cyanate, in white needles, which have a sweetish taste, dissolve sparingly in cold, easily in hot water, also in alcohol and in ether, and are resolved, at 158°, into ammonia and ditolylcarbamide. It is related to the isomeric compound obtained by Noad from nitrotolylamide, in the same manner as the true phenyl-urea to the compound which Chancel obtained by reduction of nitrobenzamide (See Carbamides, i. 754, 755.)

Tolyl-ethylcarbamide, $C^{10}H^{14}N^2O = (CO)''(C^7H^7)(C^2H^5)H^2N^2$, is obtained by direct combination of toluidine with ethylic cyanate, and separates from a boiling mixture of alcohol and water, in white crystals. It is insoluble in water, but soluble in alcohol. (Sell, *loc. cit.*)

Ditolylcarbamide, $C^{15}H^{16}N^2O = (CO)''(C^7H^7)^2H^2N^2$, is produced by boiling an alcoholic solution of ditolylsulphocarbamide with mercuric oxide, as long as mercuric sulphide is thereby separated. The filtered solution yields ditolylcarbamide in white crystals. It is likewise obtained, together with the products of decomposition of ordinary urea, by the dry distillation of monotolylcarbamide. It is insoluble in water, easily soluble in alcohol, and is decomposed by strong sulphuric acid, in the manner shown by the equation, into tolylsulphamic or sulphotolylamic acid, carbonic anhydride, and water (p. 527):

$$C^{15}H^{16}N^2O + 2H^2SO^4 = 2(C^7H^9N.SO^3) + CO^2 + H^2O.$$

Ditolylsulphocarbamide, $C^{15}H^{16}N^2S = \left.\begin{matrix}(CS)''\\ (C^7H^7)^2\\ H^2\end{matrix}\right\}N^2$, is obtained by warming a concentrated alcoholic solution of toluidine with an equal volume of carbonic disulphide, not above 80°, till the evolution of sulphydric acid ceases, distilling off the excess of carbonic disulphide, and recrystallising the remaining crystalline mass from alcohol. It is insoluble in water and in cold alcohol, has a bitter taste, and forms large acuminated prisms, which melt at 164°, and sublime without decomposition. (Sell.)

TOLYL-DIPHENYL-ROSANILINE. See Phenylamines (iv. 473).

TOLYLENE. C^7H^6.—Syn. with Benzylene (i. 577).

TOLYLENE-DIAMINE. $C^7H^{10}N^2 = \left.\begin{matrix}(C^7H^6)''\\ H^4\end{matrix}\right\}N^2$. (Hofmann, Proc. Roy. Soc. xi. 518.)—This base, first obtained as a by-product in Colin's aniline factory at Paris, is prepared by distilling dinitrotoluene with a mixture of iron-filings and acetic acid. When recently prepared, it forms crystals which become slightly coloured on exposure to the air, but may be rendered colourless again by treatment with animal charcoal. It melts at 99°, and distils without decomposition at about 280°. It is dissolved in considerable quantity by boiling water, and separates on cooling in needles, sometimes an inch long. It is easily soluble in alcohol and ether. Its solutions have an alkaline reaction.

Hydrobromate of tolylene-diamine, $C^7H^{10}N^2.2HBr$, forms short needle-shaped crystals, soluble in water and in alcohol.—The *hydrochlorate* is easily soluble in water, even at ordinary temperatures, but crystallises easily from strong hydrochloric acid.—The *chloroplatinate* forms yellow needles, very easily soluble in water.—The *sulphate*, $C^7H^{10}N^2.H^2SO^4$, forms long well-defined needles, which become reddish on exposure to the air.

Tolylene-diamine, treated with œnanthol, forms diœnanthylidene-tolylene-diamine, $C^{21}H^{24}N^2 = (C^7H^{14})^2(C^7H^6)''N^2$, as a heavy non-basic oil, soluble in alcohol, but insoluble in water. With bitter-almond-oil, in like manner, it yields dibenzylidene-tolylene-diamine, $C^{21}H^{18}N^2 = (\alpha C^7H^6)''(\beta C^7H^6)''N^2$. (Schmidt, Jahresb. 1865, p. 429.)

TOLYLENE-TRIAMINES. (De Laire, Girard, and Chapoteaut, Compt. rend. lxiii. 964; liv. 416.)—Hofmann has shown that rosaniline (iv. 468) has the composition of ditolylene-phenylene-triamine, $(C^7H^6)^2(C^6H^4)H^3N^3$, being formed by elimination of 6 at. hydrogen from a mixture of 2 at. toluidine and 1 at. aniline. Other bases of similar constitution may be obtained by the action of oxidising or dehydrogenising agents on toluidine, aniline, and mixtures of the two:

a. Tritolylene-triamine, or *Chrysotoluidine*, $C^{21}H^{21}N^3 = \left.\begin{matrix}(C^7H^6)^3\\ H^3\end{matrix}\right\}N^3$, is a yellow base, resulting from the oxidation of 3 at. toluidine:

$$3(C^7H^7)H^2N - H^6 = (C^7H^6)^3H^3N^3.$$

β. Triphenylene-triamine, or *Violaniline*, $C^{18}H^{15}N^3 = \left.\begin{matrix}(C^6H^4)^3\\ H^3\end{matrix}\right\}N^3$, is a violet base, formed, in like manner, from 3 at. aniline.

γ. Diphenylene-tolylene-rosaniline, or *Mauvaniline*, $C^{19}H^{17}N^3 = \left.\begin{matrix}(C^6H^4)^2\\ (C^7H^6)''\\ H^3\end{matrix}\right\}N^3$.—This base is formed (together with violaniline and a small quantity of rosaniline) when the aniline used is not quite free from toluidine:

$$\underset{\text{Aniline.}}{2(C^6H^5)H^2N} + \underset{\text{Toluidine.}}{(C^7H^7)H^2N} - 3H^4 = \underset{\text{Mauvaniline.}}{(C^6H^4)^2(C^7H^6)H^3N^3}.$$

Mauvaniline is a crystallised base of light-brown colour, becoming darker when heated. The crystals are hydrated, containing $2C^{19}H^{17}N^3.H^2O$. They retain their water at 120°—130°, and give it up only at a temperature at which they begin to decompose.

Mauvaniline is soluble in alcohol, ether, and benzene, insoluble in cold, very soluble in boiling water. It dissolves in acids, forming crystallisable salts, which have a bronze-green reflex, like those of rosaniline. They are slightly soluble in cold, moderately soluble in boiling water, and in strongly acidulated water. They rival the salts of rosaniline in tinctorial power, imparting a fine mauve colour to silk and wool.

Violaniline, mauvaniline, rosaniline, and chrysotoluidine, form an arithmetic series, whose common difference is CH^2. The formation of violaniline, mauvaniline, and chrysotoluidine being strictly analogous to that of rosaniline, these bodies may also be expected to result from the oxidation of commercial aniline. It is well known, indeed, that the quantity of rosaniline obtained in the preparation on the large scale is considerably less than that which corresponds to the quantity of aniline and toluidine transformed, and that there is produced, at the same time, a quantity of resinous matter, of violet to brownish-yellow colour, and possessed of basic properties. This resinous matter is a mixture of several compounds, extremely difficult to separate, and doubtless consisting in great part of the three homologues of rosaniline just mentioned. The authors have, in fact, detected mauvaniline in the residues of the preparation of rosaniline-salts; they likewise attribute the decided violet tint exhibited by certain commercial aniline-reds to the presence of mauvaniline, and the yellow tint sometimes observed in commercial rosaniline-salts to admixture of chrysotoluidine.

δ. The three atoms of typic hydrogen in each of the bases above mentioned may be replaced by alcohol-radicles, ethyl, methyl, phenyl, tolyl, &c., forming derivatives analogous to triethyl- and triphenyl-rosaniline (iv. 471, 472), and obtainable by similar methods.

ε. The secondary monamines, diphenylamine, ditolylamine, methyl-phenylamine, &c., subjected to the action of dehydrogenising agents, likewise give off 6 at. hydrogen, and yield substituted triamines of rosaniline, chrysotoluidine, and violaniline; *e.g.*:

$$\underset{\text{Ditolylamine.}}{3(C^7H^7)H^2N} - H^6 = \underset{\text{Tritolyl-chryso-toluidine.}}{\left.\begin{matrix}(C^7H^6)^3\\ (C^7H^7)^3\end{matrix}\right\}N^3}.$$

TOLYL-ETHYL-UREA. Syn. with TOLYL-ETHYL-CARBAMIDE (p. 872).

TOLYL-PHENYLAMINE. Syn. with TOLYLANILINE (iv. 454).

TOLYLSALICYLAMIDE. This name is given by Jaillard (Compt. rend. lx. 1096) to a compound obtained by heating a mixture of toluidine and salicylol to 50°, and crystallising the product from hot alcohol. It forms yellow crystals, inodorous, insoluble in water, soluble in alcohol and ether, melts at 100°, volatilises at a higher temperature, and is decomposed by alkalies. According to **Jaillard**, it has the same composition as tolylbenzamide, $C^{14}H^{13}NO$, and its hydrochlorate gives, with platinic chloride, a double salt, containing $2(C^{14}H^{13}NO.HCl)Pt.Cl^4$.

TOLYLSUCCINIMIDE, or **SUCCINOTOLUIDE.** $C^{11}H^{11}NO^2 = \left.\begin{matrix}(C^4H^4O^2)''\\ C^7H^7\end{matrix}\right\}N = C^7H^5(C^4H^4O^2)''.NH^2$.—This compound is formed by melting equal weights of succinic acid and toluidine, and crystallising the cooled mass from boiling water. It volatilises without decomposition, dissolves easily in hot water, alcohol, and ether, and separates from solution in colourless crystals.

Ditolylsuccinamide, $C^{18}H^{20}N^2O^2 = \left.\begin{matrix}(C^7H^7)^2\\ (C^4H^4O^2)''\\ H^2\end{matrix}\right\}N^2$, is the portion of the above-mentioned product insoluble in hot water; it crystallises from hot alcohol. (**Sell.**)

TOLYLSULPHUROUS BROMIDE and **CHLORIDE.** Syn. with TOLUENE-SULPHOBROMIDE and TOLUENE-SULPHOCHLORIDE (p. 859).

TOLYLSULPHUROUS HYDRIDE. Syn. with TOLUENE-SULPHUROUS ACID (p. 860).

TOLYL-THIOSINAMINE. By heating toluidine with oil of mustard to 100° for several hours, a mass is formed, which solidifies in laminæ on cooling, and may be purified by recrystallisation from alcohol. It is inodorous, insoluble in water, easily soluble in alcohol and ether, melts at 100°, and is converted, by oxide of lead or mercury, into a non-sulphuretted compound, which crystallises in needles. (**Jaillard.**)

TOMBAC. An alloy of copper and zinc containing about 80 per cent. copper. (See COPPER, ALLOYS OF, ii. 47, 49.)

TOMBAZITE. Breithaupt's name for a variety of nickel-glance from a mine near Lobenstein.

TONKA-BEANS. The fruit of *Dipterix odorata* a leguminous tree, indigenous in Guiana. They are about the size of a large almond, rather cylindrical than flat, and pointed at both ends. The outer shell is dark-brown, wrinkled, and has a fatty lustre. The beans have an aromatic bitter taste, and a very agreeable odour, like that of melilot and woodruff. They contain coumarin (ii. 93), and a fixed oil, besides sugar, gum, starch, malic acid, salts, and woody fibre (**Boullay** and **Boutron-Charlard**, J. Pharm. xi. 426; *ibid.* [3] vii. 160). They are used as a perfume, especially for snuff.

The so-called English tonka-beans (from *Dipterix oppositifolia*) are rather smaller and darker, but otherwise not essentially different from those just described.

TOPAZ. *Physalite. Pyrophysalite. Pycnite. Schorlartiger Beryl. Stangenstein.*—A tribasic silicate of aluminium, $Al^2O^3.SiO^2$, having part of the oxygen replaced by fluorine. It occurs in trimetric crystals, exhibiting the combination $P . \infty P$, $\infty\breve{P}2$, like *fig.* 265 (ii. 147), also with the basal face oP, and the face $2\breve{P}\infty$ replacing the terminal edges between P and P; frequently also with other faces subordinate. Axes $a : b : c = 0{\cdot}5285 : 1 : 0{\cdot}4770$. Angle $P : P$ (brach.) = 141° 0′; $P : P$ (macr.) = 101° 40′; $P : P$ (basal) = 87° 18′. The crystals are usually hemimorphous, the extremities being unlike. Cleavage very perfect parallel to the base. The mineral also occurs granular, coarse or fine. Hardness = 8. Specific gravity = 3·4—3·65. Lustre vitreous. Colour yellow, white, green or blue; pale. Streak uncoloured. Transparent to subtranslucent. Fracture subconchoïdal to uneven. Pyroelectric. Before the blowpipe on charcoal, it does not fuse, but when strongly heated becomes covered with small blisters, which crack as soon as formed. The pale-yellow varieties become colourless when heated, the dark-yellow become rose-red or hyacinth-red. When strongly heated in a glass tube with microcosmic salt, it exhibits the fluorine reaction. With borax it slowly fuses before the blowpipe to a colourless glass; with microcosmic salt it forms a silicious skeleton, the bead becoming opalescent on cooling; with carbonate of sodium it forms a tumid, semitransparent slag; with a large quantity of the sodium-salt, a tumefied infusible mass. It is insoluble in acids; and when digested for some time with strong sulphuric acid, it gives off hydrofluoric acid.

The analyses of topaz from Fahlun in Sweden, and Trumbull in Connecticut, by **Forchhammer** (J. pr. Chem. xxix. 294; xxx. 400), give from 34·39 to 35·66 per cent. silica, 51·88 to 55·96 alumina, and about 17 per cent. fluorine, showing that topaz may be regarded as a mixture or compound of tribasic aluminium-silicate with silico-aluminic fluoride in the proportion represented by the formula $(2Al^2F^3.SiF^4).5(Al^2O^3.SiO^2)$. The older analyses by Berzelius, Vauquelin, and Klaproth gave the amount of fluorine about 3 per cent. too low.

Topaz occurs in gneiss or granite, with tourmaline, mica, and beryl, occasionally with apatite, fluor-spar, and tin; also in talcose rock, as in Brazil, with euclase, &c., or in mica-slate. Fine topazes come from the Ural and Altai Mountains, from Miask in Siberia, and from Kamtschatka, of green and blue colours; from Villa Rica in Brazil, of deep yellow colour: blue crystals occur at Cairngorm, Aberdeenshire, and in the tin-mines of Schlackenwald, Zinnwald, and Ehrenfriedersdorf; smaller crystals also at Schneckenstein and Altenberg in Saxony, and on the Mourne Mountains in Ireland.—*Pycnite* is a massive, subcolumnar variety of topaz from Altenberg, Schlackenwald, Zinnwald, and Kongsberg.—*Physalite*, or *Pyrophysalite*, is a coarse nearly opaque variety, which intumesces when heated. It is found in yellowish-white crystals, of considerable size, at Fossum in Norway, and at Finbo and Broddbo in Finland; a crystal was found in this last locality, weighing eighty pounds. Topaz occurs in the United States, at Trumbull and Middletown in Connecticut, and at Crowder's Mountain, North Carolina.

The finer varieties of topaz are much valued as gems. The best crystals are brought from Minas Geraes in Brazil. The coarse varieties may be employed as a substitute for emery.

TOPAZ ROCK. This name was applied by Werner to a rock composed of quartz, tourmaline, lithomarge, and topaz, forming a considerable vein in the mica-slate of the Saxon Voigtland.

TOPAZOLITE. A name sometimes applied to yellow garnet.

TORBANITE, or **TORBANE HILL MINERAL.** See Coal (i. 1033).

TORBERITE. See Uranite.

TORMENTILLA. The roots of *Tormentilla erecta* were formerly used in medicine as *Red tormentilla*. They contain, in the fresh state, from 5 to 6 per cent. of a tannin, which, according to Stenhouse, forms a dark-green precipitate with ferrous sulphate, bluish-red with ferric acetate; it is also precipitated by gelatin and by tartar-emetic. It has been proposed to substitute this root for that of rhatany for use in medicine.

The leaves of the plant contain, according to Sprengel, 63 per cent. water, 33 dry vegetable substance, and 4 ash. The ash contains, in 100 pts., 12·0 per cent. potash, 3·0 soda, 22·7 lime, 2·3 magnesia, 10·3 ferric oxide, 5·1 alumina, 41·4 silica, 2·0 sulphuric anhydride, 0·5 phosphoric anhydride, and 0·8 chlorine.

TORPEDO. The electric organ of the *Torpedo Galvanii* has been examined by Schulze (Jahresb. 1859, p. 622). The aqueous extract contains a proportionally large quantity of urea and calcic phosphate, together with creatinine, syntonin, an organic body precipitable by tannin, and several compounds precipitable by chloride of zinc—some in the crystalline, others in the syrupy form. Respecting the electric properties of the torpedo, see Electricity (ii. 476).

The name *torpedo* is likewise applied to explosive engines, which are sunk in the water of harbours, and fired by electricity on the approach of a hostile vessel.

TORRELITE. Syn. with Niobite.

TORRICELLIAN VACUUM. The space above the mercury in a barometer-tube, which is free from air, but contains vapour of mercury; the tension of this vapour, however, is imperceptible at ordinary temperatures.

TOULOUCOUNA or **TULUCUNA OIL.** Syn. with Carapa Oil (i. 749).

TOULOURON OIL. A brown train-oil obtained from *Pagurus Latro*, and used by the negroes of Senegal as a remedy for rheumatism.

TOURMALINE. *Schorl. Rubellite. Indicolite. Aphrisite. Aphrite. Zeuxite.*—A well-marked group of rhombohedral double silicates, characterised geometrically and physically by hemimorphism and pyroelectricity, and chemically by the presence of boracic acid. The crystals usually exhibit the combination $\infty P2 . \frac{\infty R}{2}$, terminated by R and other rhombohedrons. The primary form may be assumed to be a rhombohedron R, having the principal axis equal to 0·4472, and the angle R : R in the terminal edges = 133° 10′; but the magnitude of the angle differs to a certain extent in the several varieties. The crystals exhibit traces of cleavage parallel to R. They are brittle, with subconchoïdal to uneven fracture.

Hardness = 7 to 7·5. Specific gravity = 2·94 to 3·3. Lustre vitreous. Colour black, brown, blue, green, red, or white; some specimens are red internally, and green externally; others red at one extremity, and green, blue, or black at the other. The crystals exhibit dichroism (iii. 670). Their streak is uncoloured. They are transparent to opaque; unlike in transparency across the prism, and in the line of the axis. Transparent tourmalines transmit light only when polarised in a plane perpendicular to their principal axis (iii. 655). The crystals are strongly pyro-electric (ii. 411).

The numerous analyses which have been made of tourmalines (for which see Rammelsberg's *Mineralchemie*, pp. 673–679; Dana's *Mineralogy*, ii. 272), show that these minerals contain, as protoxides, magnesia, ferrous oxide, manganous oxide, lime, lithia, potash, soda, and that the relative proportions of these bases, especially of the magnesia, ferrous and manganous oxides, vary within very wide limits: hence Rammelsberg, to whom the greater number of these analyses are due, divides tourmalines into magnesium-tourmalines, magnesium-iron tourmalines, iron-tourmalines, iron-manganese tourmalines, and manganese-tourmalines; the last two varieties contain lithia, the others do not. The sesquioxides contained in tourmalines are alumina, and, according to most authorities, likewise ferric and manganic oxides; according to A. Mitscherlich, however (J. pr. Chem. lxxxvi. 1), the iron and manganese in tourmalines are wholly in the state of protoxide. All tourmalines likewise contain boric oxide or anhydride, B^2O^3, which may be regarded as replacing part of the alumina. As the most general expression of the composition of tourmalines, Rammelsberg gives the formula:

$$(2\mathrm{M}^2\mathrm{O}.\mathrm{SiO}^2)\ .\ n(\mathrm{R}^2\mathrm{O}^3;\mathrm{B}^2\mathrm{O}^3)\mathrm{SiO}^2,$$

M denoting a monatomic metal (2 at. of which may of course be replaced by M''), and R a triatomic metal. Most tourmalines contain also a small quantity of fluorine, which (as in topaz) may be regarded as replacing part of the oxygen. For the full discussion of the formula, see Rammelsberg (*loc. cit.*).

The following are examples of the composition of the several varieties of tourmaline above enumerated, according to analyses by Rammelsberg:—

a. Magnesium-tourmaline, from Gouverneur, St. Lawrence County, New York: brown; specific gravity = 3·049.—*b.* Magnesium-iron tourmaline, from Texas, Lancaster County, Pennsylvania: very thin, dark-green, translucent; specific gravity = 3·043.—*c.* Iron-tourmaline, from Sonnenberg, near Andreasberg, in the Harz: specific gravity = 3·243 (the heaviest tourmaline).—*d.* Iron-manganese tourmaline, from Elba: green, often reddish or blackish at one end; specific gravity = 3·112.—*e.* Manganese-tourmaline, from Paris, in the State of Maine: dark-red; specific gravity = 3·019:

	a.	*b.*	*c.*	*d.*	*e.*
Fluorine . .	2·28	2·36	1·64	2·35	2·58
Phosphoric anhydride . .		0·20	0·12	. .	0·27

The colour of tourmalines varies according to their composition: red tourmalines (*rubellite*, *siberite*, *daourite*, *apyrite*) are those which contain lithium and manganese, with little or no iron (manganese-tourmalines); the violet-blue and green varieties generally contain lithium, iron, and manganese (iron-manganese tourmalines); the black (*schorl*) are either iron- or magnesium-iron tourmalines; the yellow and brown mostly magnesium-tourmalines. Hence the chemical characters of tourmalines vary to a considerable extent, according to their colour.

Tourmalines not containing lithia, when heated before the blowpipe, form, with strong intumescence, and more easily in proportion as they contain more iron, white or yellowish masses, which afterwards melt to white, yellowish, or grey slags. Heated with fluor-spar and acid sulphate of potassium, they give—like all other tourmalines—the reaction of boric acid. Magnesium-iron tourmalines yield, after swelling up, a white, grey, yellowish, greenish, or brown slag; iron-tourmalines, after intumescence, brown or black slags; iron-manganese tourmalines (the dark-coloured or blue) melt before the blowpipe, with difficulty and slight intumescence, to grey or brownish slags, and, when heated in a furnace, bake together to compact dark-brown masses. Green tourmalines, heated before the blowpipe, become white and opaque, melt on very thin edges to an enamel covered with small bubbles, and when heated in a crucible, form porcelain-like masses without fusing; only the green tourmaline of Brazil, and that of Chesterfield in Massachusetts, swell up before the blowpipe, and yield, partly a greyish-yellow slag, partly an unfused violet-green mass; when strongly heated in a crucible, they form an opaque brownish slag. Manganese-tourmalines generally exfoliate before the blowpipe, becoming white and opaque, and, when heated in a crucible, sometimes sinter slightly together.

---

* Manganous oxide. † Containing 0·11 manganous oxide.

At a strong red heat, all tourmalines lose several per cent. of their weight, in consequence of the escape of silicic fluoride, and perhaps also of boric fluoride. It is only after having undergone this change that the pulverised tourmaline can be decomposed by hydrofluoric acid; whereas this acid acts but slightly on the original tourmaline, and other acids still less or not at all. According to v. Kobell, pulverised tourmaline is imperfectly decomposed by sulphuric acid before fusion, almost completely after fusion.

Tourmalines are usually found in granite, gneiss, or mica-slate; they also occur in dolomite or granular limestone, and in sandstone near dykes of igneous rocks. Large black tourmalines occur in Greenland; at Hörlberg, near Bodenmais, in Bavaria; at Käringbricka, in Sweden, and near Bovey in Devonshire. Small brilliant crystals, occurring in decomposed felspar, at Andreasberg in the Harz, constitute the variety called *aphrite*. Rubellite and green tourmalines occur near Ekatherinenburg in Siberia; pink crystals are found in Elba; pale yellowish-brown crystals in talc at Windsch-Kappell in Carinthia; green at Airolo, in Switzerland; white specimens (*achroïte*) come from St. Gothard, Siberia, and Elba. Black tourmalines occur with the emery of Naxos. Magnificent red and green tourmalines have been found at Paris, in the State of Maine, some above an inch in diameter, transparent ruby-red within, surrounded by green or red at one extremity, and green at the other. (Respecting other American localities, see Dana, ii. 274.)

TOURMALINE, ARTIFICIAL. This name has been applied to sulphate of iodoquinine, on account of its optical properties. (See QUININE, p. 25.)

TOURMALINE-ROCK. TOURMALINE-SLATE. Tourmaline and quartz are found united in rocks like mica and quartz, and thus form tourmaline-rock and tourmaline-slate. The former is a crystallo-granular mixture, containing also crystals of felspar; in the latter, tourmaline, varying in structure from acicular to granular, occurs in alternate layers with granular quartz. These slates, by taking up mica, pass into mica-slate, or by taking up felspar into gneiss; the mixture called tourmaline-rock passes, in like manner, into tourmaline-granite. (Handw. d. Chem. viii. 1046.)

TOWANITE. Syn. with COPPER-PYRITES (ii. 77).

TRACHYDOLERITE. This name is applied to certain rocks, resembling both trachyte and dolerite in external appearance, and consisting of oligoclase or labradorite and amphibole or augite, with more or less magnetic iron-ore. The mixture is fine-grained, and usually forms a grey or brown mass, in which small crystals of the above-named minerals are imbedded. Specific gravity = 2·7 to 2·8. The proportion of silica in the rock is from 50 to 60 per cent. On the trachydolerite of the Siebengebirge, see Deiters (Inaugural dissertation; *De connexu inter trachyten et basalten, &c.*, Bonnæ. 1861; Jahresb. 1861, p. 1069); on that of Madeira and Porto Santo, Cochius (J. pr. Chem. xciii. 129; Jahresb. 1864, p. 872).

TRACHYTE. A felspathic rock, having a rough surface of fracture, and usually consisting of a fine-grained or compact ground mass of sanidin, oligoclase, albite, or labradorite, or two of these minerals together, enclosing crystals or crystalline particles of these felspars, also of amphibole or augite, and dark-coloured mica. When the felspathic ground-mass is decomposed, the rock becomes an indurated clay, and is then sometimes called domite; such an altered trachyte occurs on the Puy-de-Dôme. Nodules of trachyte, bound together by a trachytic cement, form trachyte-conglomerate or trachyte-breccia. Trachyte-porphyries are trachytes in which the ground-mass is more or less compact, and the imbedded crystals of sanidin are more distinct than in ordinary trachyte; the rock also frequently contains brown or black crystals of mica, and sometimes small crystals or grains of quartz. On the trachytes of the Eugenesian Mountains, near Padua, see G. v. Rath (Jahresb. 1865, p. 916); on those of Auvergne, Kossmann (*ibid.* 918).

TRAGACANTH. See GUM (ii. 955).

TRAGOPOGON. The goat's-beard, *Tragopogon pratensis*, a composite plant of tribenzylamine remains undissolved, and the solution contains, together with sal-ammoniac, the hydrochlorate of benzylamine, and probably also of dibenzylamine. The hydrochlorate of benzylamine is separated from the more soluble portion by fractional crystallisation; and the free base separated from this salt by potash is dissolved in ether, freed from ether by evaporation, dehydrated by fused potash out of contact with the air, and then distilled—the portion which gives over at 182° being collected apart. For complete purification, it is converted into the solid carbonate by exposure to a stream of dry carbonic anhydride; the carbonate is washed with anhydrous ether, and dissolved in hydrochloric acid; and the crystallised hydrochlorate is decomposed with potash as above.

Benzylamine, thus prepared, is a colourless liquid, not altered by light, and boiling at 182°—183°. (Toluidine, described, at vol. i. p. 575, as benzylamine, is crystalline at ordinary temperatures, and melts at · °). It mixes with water in all proportions (toluidine is but slightly soluble in cold water), and is separated therefrom by potash, with faint yellowish colour. It absorbs carbonic anhydride rapidly, forming a crystalline compound; has a strong alkaline reaction; forms white fumes with hydrochloric acid, and unites with acids, producing rise of temperature. Altogether, it appears to be a stronger base than toluidine.—*Hydrochlorate of benzylamine*, $C^7H^9N.HCl$, crystallises in striated tables; the *chloroplatinate* in orange-coloured laminæ.

Dibenzylamine, $(C^7H^7)^2HN$, isomeric with benzyltoluidine, has not been isolated, but appears to be formed, together with mono- and tri-benzylamine, in the process above described.

Tribenzylamine, $(C^7H^7)^3N$, isomeric with dibenzyltoluidine (p. 866), has been already described (i. 574).

Phenyl-benzylamine, $C^{13}H^{13}N = \left.\begin{matrix}C^6H^5\\ C^7H^7\\ H\end{matrix}\right\}N$. (Fleischer, Ann. Ch. Pharm. cxxxviii. p. 225; Bull. Soc. Chim. [1866], ii. 235.)—This base, isomeric with Hofmann's tolylaniline (iv. 454), is produced by mixing aniline with benzylic chloride (boiling at 170°).* The mixture becomes hot, and deposits white crystals, consisting of hydrochlorate of aniline, together with phenyl-benzylamine:

$$C^7H^7Cl + 2C^6H^7N = C^6H^7N.HCl + C^{13}H^{13}N.$$

The mixture must be heated to 160° for twenty-four hours, to complete the reaction; and on dissolving out the hydrochlorate of aniline from the product by water, the phenyl-benzylamine remains as an oil, which is converted by hydrochloric acid into crystals of the hydrochlorate, $C^{13}H^{13}N.HCl$. On decomposing this salt with soda, and distilling the liberated base under a pressure of 45 millimetres, the greater part passes over, between 200° and 220°, in the form of an oily liquid, which solidifies at a low temperature, and may be purified by pressure between bibulous paper, and recrystallisation from boiling alcohol.

Phenyl-benzylamine crystallises in colourless four-sided prisms, insoluble in water, but soluble in alcohol and in ether. It melts at 32°, remains in a state of surfusion at 12°, and boils under the ordinary pressure at a temperature above 310°. (Tolylaniline melts at 87°, and boils at 334°).—The *hydrochlorate*, $C^{13}H^{13}N.HCl$, forms colourless crystals.—The *oxalate*, $(C^{13}H^{13}N)^2.C^2H^2O^4$, forms white laminæ.—The base forms, with *chloride of cadmium*, the compound $C^{13}H^{13}N.CdCl^2$.

Phenyl-benzylamine, fused with mercuric chloride, forms at first a green mass, which dissolves in alcohol with fine blue colour; but by the prolonged action of heat, this mass assumes a dark colour, and then forms with alcohol a crimson solution.

Phenyl-benzylamine treated with *chloride of benzoyl* forms phenyl-benzyl-benzamide, $(C^6H^5)(C^7H^7)(C^7H^5O)N$, which crystallises in oblique prisms.

TOLUOL. Syn. with TOLUENE.

TOLUOLIC ACID. Syn. with TOLUIC ACID.

TOLUONITRILE. Syn. with BENZYLCYANIDE (i. 573).

TOLUOSALICYL, or **TOLUOSALICYLOL.** See SALICYLOL (p. 170).

TOLUOXYL. C^8H^7O.—The radicle of toluic acid and its derivatives. (Footnote, p. 869.)

TOLURIC ACID. $C^{10}H^{11}NO^3 = \left.\begin{matrix}H\\ (C^2H^2O)''\\ C^8H^7O\\ H\end{matrix}\right\}\begin{matrix}N\\ O\end{matrix}$.—*Toluglycic Acid. Glycocol-toluic Acid.* (Kraut, Ann. Ch. Pharm. xcviii. 360.)—An acid homologous with

---

* Chlorotoluene (according to Fleischer), but the boiling-point shows that the compound used was really benzylic chloride (p. 85[illegible]).

the suborder *Cichoraceæ*, contains, according to Sprengel (J. f. techn., Chem. viii. 363), in 100 pts. of the fresh plant, 79·0 water, 19·9 organic substance, and 1·10 ash. The ash free from carbonic acid contains, in 100 pts.:

K^2O.	Na^2O.	CaO.	MgO.	Al^2O^3.	Fe^2O^3.	Mn^2O^3.	SiO^2.	SO^3.	P^2O^5.	Cl.
24·6	2·4	33·9	7·4	1·4	0·3	0·2	3·9	8·6	9·8	7·4

TRANSPIRATION. A term applied by Graham to the passage of gases and liquids through capillary tubes. (See GASES, ii. 820; and LIQUIDS, iii. 722.)

TRANSUDATION. A physiological term, denoting the passage of liquids from the bloodvessels, without laceration or perforation, into closed or open cavities of the body, into the parenchyma of the organs, or sometimes on to the surface of the body. (See SEROUS FLUIDS, p. 235.)

TRAP. A geological term, which was applied to melaphyre, basalt, dolerite, diabase, gabbro, &c., and generally to more or less compact, dark-coloured, eruptive rocks, before the several species were distinguished according to their constituents. *Trap-porphyry* is an old name for the so-called greenstone-porphyries, melaphyres, and phonolites.

TRAPA. The mineral constituents of this water-plant and of the water of a pond near Nürnberg, in which it grows, have been examined by Gorup-Besanez (Ann. Ch. Pharm. cxviii. 220; Jahresb. 1861, p. 751).—A is the composition of the ash of the plant gathered in June (stem-leaves, radical leaves, and roots); B, that of the plant gathered in May; C that of the fruit (the whole in percentages, after deduction of charcoal and sand); D, the composition, in 100 pts., of the ignited water-residue (amounting to 0·8044 pt. in 10,000 pts. of water):

	Ash per cent.	SiO^2.	Fe^2O^3	Mn^3O^4.	CaO.	MgO.	K^2O.	Na^2O.	Cl.	SO^3.
A.	15·92	27·34	23·40	14·70	17·65	5·15	6·06	2·71	0·46	2·53
B.	29·46	28·66	29·62	7·57	14·91	7·56	6·89	1·41	0·65	2·73
C.	7·75	4·84	68·60	9·63	9·77	0·91	1·26	0·62	0·41	3·92
D.	. .	1·90	1·11	0·15	42·24	18·08	9·07	9·21	1·18	17·03

From the considerable proportion of iron- and manganese-oxides in the ash of the plant, and from the different proportions of the several constituents in the plant-ash and in the water, Gorup-Besanez concludes that water-plants possess the power of selecting the constituents of the nutritive matters presented to them.

TRASS. A volcanic mass resembling pumice, and containing silicates decomposable by slaked lime, so that it is available for the preparation of cements. (See SILICATES OF CALCIUM, p. 251.)

TRAVERSELLITE. A name applied by Scheerer (Pogg. Ann. xciii. 109) to certain pseudomorphs of hornblende after augite (regarded by him as paramorphs, iv. 350), occurring at Traversella in Piedmont. These pseudomorphs are remarkable for retaining the form of the augite crystals, while the substance, in consequence of the transformation, has acquired a fibro-crystalline structure, so that the augitic crystals are made up of parallel fibres.

TRÆVERTINO. Calcareous tufa, occurring at Tivoli, Viterbo, Ascoli, and other places in Central Italy.

TREHALA, or **TRICALA.** A substance imported from Persia, and consisting of the hollow cocoons of a coleopterous insect (*Larinus maculatus*). The larva of this insect eats the branches of *Echinops persica*, for the sake of the sugar, starch, and gum contained in them, and afterwards voids these substances to form its cocoon. The organic portion of trehala consists, according to Guibourt (J. Pharm. [3], xxxiv. 81; Jahresb. 1858, p. 485), of 66·5 per cent. starch, 4·6 sparingly soluble gum, 28·9 sugar, and bitter principle. The sugar, called trehalose, appears to be identical with the mycose of ergot-of-rye (iii. 1698). The starch differs from that of the potato, being more like that of sago, or still more like the insoluble portion of gum-tragacanth. Trehala yields 4·6 per cent. ash, of which 3 pts. are soluble in water, and consist of alkaline carbonates, sulphates, and chlorides, with small quantities of phosphate; 1·4 pts. insoluble, consisting chiefly of calcic carbonate with a little ferric phosphate; and 0·2 sand. Trehala has a sweetish taste, swells up in water, and is converted into a thick mucilaginous paste.

TREHALOSE. See MYCOSE (iii. 1068).

TREMELLA. A genus of gelatinous algæ. *Tr. mesenterica* was found by Brandes to contain, in the dry state, 84 pts. of a substance which swelled up in water, and 5 pts. of a peculiar crystallisable resinous body, called tremellin, but not further investigated. *Tr. Nostoc* contains, in the fresh state, 97 per cent. water and 2·5 dry substance; the ash consists mainly of potassium-salts. (Braconnot.)

TREMENHEERITE. A name given by Piddington to a black, scaly, metallically lustrous mineral, probably an impure graphite, containing 85·7 per cent. carbon, together with earthy matters, sulphide of iron, and water. (Dana, ii. 30.)

TREMOLITE. A subspecies of hornblende (iii. 169).

TRI. In this Dictionary the syllable *tri*, prefixed to the name of a radicle occurring in any compound, denotes that the compound in question contains three atoms of that radicle: *e.g.*, trichloride of bismuth = $BiCl^3$; trioxide of antimony, Sb^2O^3; trisodic phosphate, Na^3PO^4; triethylamine, $(C^2H^5)^3N$, &c. The prefix *ter* is often used in the same sense. (See NOMENCLATURE, iv. 125, 127.)

Individual tri-compounds are, for the most part, described under the several general headings: e. g., *trichloride of bismuth* under BISMUTH, CHLORIDES OF; *trisodic phosphate* under PHOSPHATES OF SODIUM; *triethylamine* under ETHYLAMINES, &c.

TRIALLYL-SULPHIODIDE. $(C^3H^5)^3SI$. *Triallylsulfiniodür.*—This compound is obtained by heating allylic sulphide with methylic iodide in prismatic crystals, soluble in water, and forming an alkaline liquid with silver-oxide. (Cahours, Jahresb. 1865, p. 476.)

TRIAMYL-GLYCERIN, $C^{18}H^{38}O^3 = \left.\begin{matrix}(C^3H^5)'''\\(C^5H^{11})^3\end{matrix}\right\}O^3$, appears to be produced by heating 1 vol. acrolein, 3 vols. amylic alcohol, and 0·5 vol. acetic acid, to 110° for twelve hours. It is decomposed by distillation. (Alsberg, Jahresb. 1864, p. 495.)

TRIAMYLIDENE. See TRIOXAMYLAMINE.

TRIANOSPERMA. In the root of *Trianosperma ficifolia*, a climbing cucurbitaceous plant, indigenous in Brazil, Peckholt (Arch. Pharm. [2], cxiii. 104) found a drastic bitter principle (*toguyin*), a small quantity of a body slightly soluble in alcohol and water, insoluble in ether, and crystallising in pointed needles (*trianospermin*), and another (*trianospermitin*), crystallising in white grains, soluble in ether, but insoluble in alcohol and in water, besides several resins.

TRICALA. Syn. with TREHALA (p. 878).

TRICAPRONYLAMINE. See TRIŒNANTHYLAMINE.

TRICARBALLYLIC ACID. $C^6H^8O^6 = \left.\begin{matrix}(C^6H^5O^3)'''\\H^3\end{matrix}\right\}O^3$. Maxwell Simpson, Proc. Roy. Soc. xii. 236; xiv. 77; Chem. Soc. J. xviii. 331.—Wichelhaus, Ann. Ch. Pharm. cxxxii. 60.—Hlasiwetz, Zeitschr. Ch. Pharm. 1864, p. 734; Jahresb. 1864, p. 395.)—A tribasic acid, formerly called *carballylic acid*, discovered by Maxwell Simpson, who obtained it by the action of potash upon allylic tricyanide:

$$C^3H^5(CN)^3 + 3KHO + 3H^2O = C^6H^5K^3O^6 + 3NH^3.$$

Dessaignes (Compt. rend. lv. 510), by treating aconitic acid with sodium-amalgam, obtained a peculiar acid, which, however, he did not succeed in preparing in the pure state; and this acid has been shown by Wichelhaus to be identical with tricarballylic acid. Lastly, Hlasiwetz has obtained the same acid by the action of sodium-amalgam on aconitic ether.

Preparation.—1. From Allylic tricyanide.—1 at. allylic tribromide and 3 at. pure potassium cyanide are heated to 100° in a closed flask for sixteen hours with a large quantity of alcohol, and the decanted alcoholic solution is boiled with potassium-hydrate as long as ammonia is evolved. The alcohol is then distilled off; the remaining potassium-salt decomposed by nitric acid; the dried mass exhausted with alcohol; and the acid remaining after evaporation of the alcohol, first converted into an ammonium-salt, then into the less soluble silver-salt. By decomposing the latter with sulphydric acid, the tricarballylic acid is obtained pure (Simpson).—2. From Aconitic acid.—The sodium-salt obtained by the action of sodium-amalgam on aconitic acid is precipitated with acetate of lead; the washed precipitate is decomposed with sulphydric acid; the acid thereby liberated, is repeatedly crystallised, and then converted into a silver-salt, to free it from obstinately adhering resinous substance, and this salt is decomposed by sulphydric acid (Wichelhaus).—When ethylic aconitate is mixed with a quantity of sodium-amalgam (containing 0·8 per cent. sodium), sufficient to form a thick unctuous mass, the mixture being cooled from time to time, and this mass is treated with ether, the ethereal solution boiled with potash, then neutralised and precipitated with acetate of lead, a lead-salt is obtained, which, when decomposed by sulphydric acid, yields tricarballylic acid. (Hlasiwetz.)

Properties.—Tricarballylic acid forms colourless crystals, which (according to Miller's determination) are trimetric, and exhibit the combination $\infty\breve{P}\infty \,.\, \infty P \,.\, \frac{1}{2}\breve{P}\infty \,.\, \infty\breve{P}2 \,.\, 2\breve{P}2$. Angle $\infty\breve{P}\infty : \frac{1}{2}\breve{P}\infty = 113° 34'$; $\frac{1}{2}\breve{P}\infty : \frac{1}{2}\breve{P}\infty = 131° 52'$; $\infty\breve{P}\infty$

$: \infty P = 134° 0'; \infty P : \infty P = 92° 0'; \infty\breve{P}\infty : \infty\breve{P}2 = 152° 38'; \infty\breve{P}\infty : 2\breve{P}2 = 142° 19'; \infty P : 2\breve{P}2 = 147° 37'; \infty\breve{P}2 : 2\breve{P}2 = 153° 1'$. The crystals cleave perfectly parallel to $\infty\breve{P}\infty$. The acid is easily soluble in water and in alcohol, sparingly soluble in ether, and has an agreeably acid taste. It resembles succinic acid in not being decomposed by nitric acid, and in forming, after neutralisation, a red-brown precipitate with ferric chloride; but it is distinguished from that acid by melting at 158°, and decomposing at a higher temperature. (Simpson.)

Tricarballylates.—The neutralised solution of the acid gives precipitates with the chlorides of barium and calcium only after addition of alcohol.—The *barium-salt*, $C^{12}H^{10}\overset{''}{Ba}{}^3O^{12}.6H^2O$, gives up its water at 130° (Hlasiwetz).—The *calcium-salt*, $C^{12}H^{10}\overset{''}{Ca}{}^3O^{12}.4H^2O$, is a white, amorphous, slightly soluble powder.—The *cupric salt*, $C^{12}H^{10}\overset{''}{Cu}{}^3O^{12}$, is a bluish-green, the *lead-salt*, $C^{12}H^{10}\overset{''}{Pb}{}^3O^{12}$, a white precipitate. The aqueous solution of the acid, boiled with recently precipitated *mercuric oxide*, yields a filtrate, which on evaporation deposits white crystals, having a silvery lustre.—The *silver-salt* contains $C^6H^5Ag^3O^6$.—The *sodium-salts* of tricarballylic acid are easily soluble, and difficult to crystallise.—The *disodic salt* has probably the composition $C^6H^6Na^2O^6.2H^2O$. (Simpson.)

TRICARBALLYLIC ETHERS. The *ethylic ether*, $\left.\begin{matrix}C^6H^5O^3\\(C^2H^5)^3\end{matrix}\right\}O^3$, is formed by passing hydrochloric acid gas into a solution of tricarballylic acid in absolute alcohol, and distilling the product, after freeing it from excess of alcohol. It is a colourless liquid, boiling between 295° and 305°, slightly soluble in water, and having a sharp taste. (Simpson.)

The *amylic ether*, $\left.\begin{matrix}(C^6H^5O^3)'''\\(C^5H^{11})^3\end{matrix}\right\}O^3$, prepared in like manner, is a heavy oily liquid, having a sharp taste, and a very high boiling-point. (Simpson.)

Glycerin-tricarballylic acid, $\left.\begin{matrix}(C^6H^5O^3)'''\\(C^3H^5)'''\\H^4\end{matrix}\right\}O^5$?, is formed by heating tricarballylic acid with twice its weight of glycerin to 200° for several hours. On neutralising the product with baryta, and treating the salt left on evaporation with absolute alcohol, to remove the excess of glycerin, a barium-salt is obtained, which appears to have the composition $\left.\begin{matrix}(C^6H^5O^3)'''\\(C^3H^5)'''\\Ba''H^2\end{matrix}\right\}O^6$. (Simpson.)

TRICHALCITE. $\overset{''}{Cu}{}^3As^2O^8.5H^2O$.—A cupric arsenate, allied to tyrolite, occurring in stellate groups and dendritic crusts on fahl-ore at an unnamed locality in Siberia.

It has a verdigris-green colour and silky lustre; hardness = 2. When heated in a tube, it decrepitates very strongly, gives off a large quantity of water, and becomes dark-brown. The dehydrated mineral melts to a bead on charcoal, in the outer blowpipe-flame; in the inner flame it gives off arsenic vapours, and is reduced to granules of copper. It dissolves easily and completely in hydrochloric and in nitric acid, without evolution of gas. (R. Hermann, J. pr. Chem. lxxiii. 212.)

TRICHOPYRITE. Syn. with CAPILLARY PYRITES or NATIVE SULPHIDE OF NICKEL (iv. 42).

TRICLASITE. Syn. with FAHLUNITE (ii. 615).

TRIDACIUM. Syn. with THRIDACIUM (p. 788).

TRIDECYL, HYDRIDE OF. $C^{13}H^{28} = C^{13}H^{27}.H$. *Hydride of Cocinyl.*—A hydrocarbon of the marsh-gas series, occurring in American petroleum. It boils at 216°—218°, has a strong turpentine-like odour, burns with a very smoky flame, and is converted by chlorine into chloride of tridecyl, $C^{13}H^{27}Cl$. (Pelouze and Cahours, Jahresb. 1863, p. 530.)

TRIETHYLGLYCERIN, or **TRIETHYLIN.** $C^9H^{20}O^3 = \left.\begin{matrix}(C^3H^5)'''\\(C^2H^5)^3\end{matrix}\right\}O^3$. — This compound, which Reboul and Lourençço obtained by treating diethyl-chlorhydrin with sodium-ethylate (ii. 884), is likewise produced by heating 1 vol. acrolein, 1 vol. alcohol, and 0·5 vol. acetic acid to 100°; also, in small quantity, by gently heating a mixture of acrolein and alcohol saturated with sulphurous acid gas; but in this case brown resinous products are likewise formed.

Triethylin is a liquid having a pleasant ethereal odour, somewhat soluble in water, boiling at 186°, and of specific gravity 0·8955 at 15°. (Alsberg, Jahresb. 1865, p. [illegible]5.)

TRIETHYLSULPHINE. See the next article.

TRIETHYLSULPHUROUS COMPOUNDS. (A. v. Oeffele, Chem. Soc. J. xvii. 106; Ann. Ch. Pharm. cxxxii. 82; Jahresb. 1864, p. 478.—Cahours, Ann. Ch. Pharm. cxxxv. 352; cxxxvi. 151; Jahresb. 1865, p. 476.—Dehn, Ann. Ch. Pharm. Suppl. iv. 83; Jahresb. 1865, p. 479.)—Ethylic monosulphide, $(C^2H^5)^2S$, and ethylic iodide, when heated together, unite and form triethylic sulphiodide, $(C^2H^5)^3SI$; this compound, decomposed by moist oxide of silver, yields the corresponding hydroxylate, $(C^2H^5)^3S(HO)$; and from this, which is a strong base, the corresponding chloride, sulphate, nitrate, &c., may be prepared in the usual way. (v. Oeffele.)

Bromide and chloride of ethyl unite, in like manner, with ethylic sulphide, but less readily than the iodide. (Cahours.)

Triethylic sulphiodide is also produced by the action of ethylic iodide on ethylic sulphydrate (mercaptan), or of hydriodic acid on ethylic sulphide (Cahours), thus:

$$C^2H^5.H.S + 2C^2H^5I = (C^2H^5)^3SI + HI.$$
$$2(C^2H^5)^2S + HI = (C^2H^5)^3SI + C^2H^5.H.S.$$

Triethylic sulphobromide is further produced, together with other sulphobromides of ethyl and ethylene, by heating ethylic sulphide with ethylenic bromide and water, the reaction taking place by several stages, as follows:

$$\underset{\substack{\text{Ethylic}\\\text{sulphide.}}}{(C^2H^5)^2S} + \underset{\substack{\text{Ethylenic}\\\text{bromide.}}}{C^2H^4Br^2} = \underset{\substack{\text{Ethylenic}\\\text{sulphide.}}}{(C^2H^4)S} + \underset{\substack{\text{Ethylic}\\\text{bromide.}}}{2C^2H^5Br.}$$

$$\underset{\substack{\text{Ethylenic}\\\text{sulphide.}}}{C^2H^4S} + \underset{\substack{\text{Ethylenic}\\\text{bromide.}}}{C^2H^4Br^2} = \underset{\substack{\text{Ethylenic}\\\text{sulphodibro-}\\\text{mide.}}}{(C^2H^4)^2SBr^2.}$$

$$\underset{\substack{\text{Ethylic}\\\text{sulphide.}}}{(C^2H^5)^2S} + \underset{\substack{\text{Ethylic}\\\text{bromide.}}}{C^2H^5Br} = \underset{\substack{\text{Triethylic}\\\text{sulphobro-}\\\text{mide.}}}{(C^2H^5)^3SBr.}$$

$$\underset{\substack{\text{Ethylic}\\\text{sulphide.}}}{(C^2H^5)^2S} + \underset{\substack{\text{Ethylenic}\\\text{bromide.}}}{C^2H^4Br^2} = \underset{\substack{\text{Ethylene-diethylic}\\\text{sulphodibromide.}}}{(C^2H^4)(C^2H^5)^2SBr^2.}$$

The mode of separating these products will be described further on.

The constitutions of these triethylic sulphur-compounds may be represented in three different ways. The iodide, for example, may be regarded:

α. As triethylic sulphiodide, $(C^2H^5)^3\left\{\begin{matrix}S''\\I\end{matrix}\right.$.

β. As iodide of triethylsulphine, $(C^2H^5)^3S'''.I.$

γ. As sulphurous triethiodide, $S^{iv}\left\{\begin{matrix}(C^2H^5)^3\\I\end{matrix}\right.$.

In the first of these formulæ the sulphur is diequivalent, in the second triequivalent, and in the third tetraequivalent, as in sulphurous acid, $\left.\begin{matrix}S^{iv}\\H^2\end{matrix}\right\}O^3$. The last is, perhaps, the most probable view of the constitution of these bodies.

In the ethylenic sulphodibromide, obtained by Dehn, in the manner above mentioned, the sulphur may, in like manner, be regarded as hexequivalent, as in sulphuric acid; thus:

$$(C^2H^4)^2SBr^2 = \text{Sulphuric Diethylene-dibromide, } S^{vi}\left\{\begin{matrix}(C^2H^4)''\\(C^2H^4)''.\\Br^2\end{matrix}\right.$$

$$(C^2H^4)(C^2H^5)^2SBr^2 = \text{Sulphuric Ethylene-diethyldibromide, } S^{vi}\left\{\begin{matrix}(C^2H^4)''\\(C^2H^5)^2.\\Br^2\end{matrix}\right.$$

Sulphurous Bromotriethide, $S(C^2H^5)^3Br$.—This compound is produced, as above stated, by heating 1 at. ethylic sulphide with 1 at. ethylic bromide, to 130°—140°, for eight or ten hours. It crystallises in colourless rhombic needles, is extremely soluble in water, sparingly soluble in alcohol, insoluble in ether. (Cahours; Dehn.)

Sulphurous Chlorotriethide, $S(C^2H^5)^3Cl$.—Ethylic chloride heated to 100° for sixty hours with ethylic sulphide yields only traces of this compound (Cahours). Dehn prepares it from the mixture of products obtained by heating ethylic sulphide with ethylenic bromide (*supra*) as follows:—The watery portion of the product, containing sulphurous bromotriethide, sulphuric dibromo-diethylenide, and sulphuric dibromo-ethylene-diethide, is separated from the oily layer (containing diethylenic sulphide), and evaporated; the residue is redissolved in water; the filtrate digested with recently-precipitated silver-oxide, and a small quantity of silver-sulphide; and the liquid (freed from silver and sulphuric acid) is supersaturated with hydrochloric acid, concentrated, and fractionally precipitated with platinic chloride. The first scanty precipitates thereby obtained consist of the chloroplatinates of sulphuric dichloro-diethylenide, $S(C^2H^4)^2Cl^2.PtCl^4$, and sulphurous dichloro-ethylene-diethide, $S(C^2H^4)(C^2H^5)^2Cl^2.PtCl^4$; finally, the chloroplatinate of sulphurous chlorotriethide crystallises out; and this salt, decomposed by sulphydric acid, yields sulphurous chlorotriethide.

Sulphurous chlorotriethide volatilises with vapour of water, deliquesces in moist air, is insoluble in ether, very slightly soluble in alcohol, and crystallises from a syrupy aqueous solution in white needles. It unites with metallic chlorides.—The *chloromercurate*, $S(C^2H^5)^3Cl.4HgCl^2$, crystallises in needles or laminæ, which dissolve in 65·8 pts. water at 20° (or in 8 pts. at 80°), melt and partially sublime at a temperature a little above 100°.—The *chlorostannate* is a very soluble salt, crystallising in needles. (Dehn.)

The *chloroplatinate*, $2S(C^2H^5)^3Cl.PtCl^4$, prepared as above, crystallises from a hot saturated solution in small light red needles, and by slow cooling of a warm non-saturated solution in garnet-red, well-developed crystals, which (according to A. Knop's determination) are monoclinic, and usually exhibit the combination $\infty P . oP . \infty P\infty . +P\infty$, the last two faces being subordinate, and sometimes wanting, whereby the crystals acquire a rhombohedral character. Ratio of axes, $a : b : c = 0·6745 : 1 : 1·1068$. Angle $b : c = 55° 6'$; $\infty P : \infty P$ (clinod.) $= 78° 52'$; $\infty P : oP = 68° 40'$ and $111° 20'$; $oP : +P\infty = 152° 0'$; $\infty P : \infty P\infty = 129° 36'$. The crystals melt at about 170°, dissolve in 30 pts. water at 20°, in 3 to 4 pts. at 100°, are nearly insoluble in alcohol, and quite insoluble in ether. (Dehn.)

Sulphurous Hydroxyltriethide, $S^{iv}\left\{\begin{matrix}(C^2H^5)^3\\HO\end{matrix}\right.$, or *Hydrate of Triethylsulphine*, $(C^2H^5)^3S.HO$, prepared by agitating or boiling the iodide with recently-precipitated silver-oxide, forms a strongly alkaline solution, which quickly absorbs carbonic acid, precipitates metallic salts like hydrate of potassium, and dries up over oil of vitriol to a crystalline, extremely deliquescent mass (v. Oeffele). According to Dehn, it dissolves the skin like caustic potash, eliminates ammonia from its salts when warmed with them, emitting at the same time a slight odour of ethylic sulphide: forms a green precipitate with cupric sulphate, black at the boiling heat; white with zinc-sulphate and lead-acetate, the precipitate in either case being insoluble in excess; with alum, &c. it forms a gelatinous precipitate, easily soluble in excess.

Sulphurous Iodotriethide, $S(C^2H^5)^3I$, is prepared by heating equivalent quantities of ethylic sulphide and iodide to 105°—110°; or 1 at. mercaptan, 2 at. ethylic iodide, and 1 at. absolute alcohol to 140°. It separates from alcoholic solution in small crystals, belonging to the trimetric system, and exhibiting the combination $\infty\bar{P}\infty . \bar{P}\infty . \breve{P}\infty . \infty P$, often tabular from predominance of $\infty\bar{P}\infty$, and with the faces $\breve{P}\infty$ generally occurring hemihedrally. The salt dissolves easily in water and in hot alcohol, but is nearly insoluble in ether; when heated above 100°, it melts, and decomposes into ethylic sulphide and iodide, without separation of iodine.—When the ether-alcoholic mother-liquor remaining in the preparation of the iodide, and containing a large quantity of free iodine, is shaken up with mercury, the compound $S(C^2H^5)^3I.HgI^2$ is formed, and crystallises from alcohol in light-yellow needles or laminæ, sparingly soluble in water. (Dehn.)

Sulphurous Nitratotriethide, $S^{iv}\left\{\begin{matrix}(C^2H^5)^3\\NO^3\end{matrix}\right.$, or *Nitrate of Triethylsulphine*, $(C^2H^5)^3.SNO^3$, obtained by treating the hydrate with nitric acid, forms deliquescent needles, uniting in radiate laminæ; it combines with nitrate of silver, forming the scaly double salt, $S(C^2H^5)^3(NO^3).AgNO^3$, sparingly soluble in cold water and in alcohol.

Sulphurous Sulphatotriethide, $\overset{''''}{S}{}^2\left\{\begin{matrix}(C^2H^5)^6\\(SO^4)''\end{matrix}\right.$, or *Sulphate of Triethylsulphine*, $[(C^2H^5)^3S]^2.SO^4$, obtained by decomposing the chloride with silver-sulphate, forms indistinct crystalline aggregates, easily soluble in water, sparingly in alcohol.

Acetate.—When sulphurous bromotriethide is decomposed with acetate of lead, and the filtrate freed from lead by sulphydric acid, crystalline crusts are formed, which separate from alcohol covered with a layer of ether, in large crystals containing bromine—perhaps a compound of sulphurous bromotriethide with sulphurous acetotriethide; and by completely removing the bromine with acetate of silver, the acetotriethide, or acetate of triethylsulphine, $(C^2H^5)^3S(C^2H^3O^2)$, is obtained as a gummy mass, slightly soluble in absolute alcohol, and precipitated therefrom in flocks by ether. (Dehn.)

Sulphurous Iodomethodiethide and *Iodo-amyldiethide* are obtained, like sulphurous iodotriethide, by heating ethylic sulphide with methylic or amylic iodide. The former, treated with silver-oxide, yields a deliquescent hydrate; and from this a platinum-salt may be obtained, crystallising in needles, and containing $2CH^3(C^2H^5)^2SCl.PtCl^4$. (Cahours; Dehn.)

TRIETHYL-TRITYLPHYCITE. See Tritylphycite (p. 895.)

TRIFOLIUM. The ash of three species of this genus, used as fodder for cattle—viz., *Tr. pratense*, common clover (I.), *Tr. pratense perenne* (II.), and *Tr. medium* (III.)—has been analysed by Way and Ogston (Roy. Agr. Soc. J. xi. [2], 536; Jahresb. 1850, p. 668), with the following results:

	I.	II.	III.
Water, in 100 pts. of air-dried substance . . .	81·0	81·0	78·6
Ash per cent. in dry substance	9·56	8·45	7·97
Sulphur per cent. in dry substance	0·27	0·10	0·20

Composition of the Ash in 100 *pts.*

	K^2O.	Na^2O.	CaO.	MgO.	Fe^2O^3.	SO^3.	SiO^2.	CO^2.	P^2O^5.	KCl.	NaCl.
I.	36·4	. .	22·6	4·1	0·2	1·8	0·6	23·5	6·7	2·4	1·5
II.	22·1	2·8	26·6	10·2	0·3	2·1	1·1	22·7	8·5	. .	3·4
III.	34·7	. .	24·5	4·5	0·2	1·1	0·6	25·5	5·4	0·8	2·5

Way (Roy. Agr. Soc. J. xiv. [1], 171), has also determined the percentage composition of the following species:

	Water.	Albumin.	Fat.	Sugar.	Cellulose.
Tr. pratense	81·0	4·3	0·69	8·4	3·7
Tr. pratense perenne . . .	81·0	3·6	0·78	8·0	4·9
Tr. incarnatum	82·1	2·9	0·67	6·7	5·8
Tr. medium	74·1	6·3	0·92	9·4	6·2
Tr. procumbens	83·5	3·4	0·77	7·2	3·7
Tr. repens	79·7	3·8	0·89	8·1	5·4

Völcker (Scott. Agr. Soc. J., July 1853), gives the following composition: No. I. for *Tr. pratense* (red clover); No. II. for *Tr. repens* (white clover); No. III. for *Tr. hybridum* (Alsike clover):

	I.	II.	III.
Water	80·6	83·6	76·7
Nitrogenous substance . .	3·6	4·5	4·8
Non-nitrogenous substance .	13·8	10·2	16·4
Ash	2·0	1·6	2·0

100 pts. of the dry seed of *Tr. pratense* give 4·68 pts. ash, of which 1·21 is soluble in water, 3·19 soluble in hydrochloric acid, and 0·28 consists of silica; 14·5 grms. of the air-dried plant of *Tr. pratense* grown in sand yielded 0·96 grm. ash, and the same quantity of the plant grown in artificial soil yielded 1·6 grm. ash, containing respectively:

	In sand.	In artificial soil.
Soluble in water	0·52	0·66
Soluble in hydrochloric acid .	0·35	0·94
Silica	0·09	0·08
	0·96	1·68

TRIGENIC ACID. $C^4H^7N^3O^2 = (CN)^2O.C^2H^3(NH^4)O$. (Wöhler and Liebig, Ann. Ch. Pharm. lix. 296.)—This acid, containing the elements of cyanic anhydride and aldehyde-ammonia, is obtained, together with other products, by passing the vapour of cyanic acid over aldehyde. The action is violent, and therefore, to avoid projection, only a few grammes of aldehyde should be used, and the vessel kept cool with ice. The mass soon enters into ebullition, giving off carbonic anhydride, and concretes into a thick substance, like calcined borax; frequently also a syrupy mass is obtained, in which crystalline crusts gradually form. This product contains trigenic acid, cyamelide, aldehyde-ammonia, and perhaps other accidental products. On dissolving it in moderately strong hydrochloric acid, boiling the solution as long as vapours of aldehyde continue to go off, and then filtering, the trigenic acid crystallises out on cooling; if yellow, it must be decolorised with animal charcoal. Its formation may be represented by the equation:

$$\underset{\text{Aldehyde.}}{C^2H^4O} + \underset{\text{Cyanic acid.}}{3CNHO} = \underset{\text{Trigenic acid.}}{C^4H^7N^3O^2} + CO^2.$$

Trigenic acid crystallises in small prisms, slightly soluble in water, nearly insoluble in alcohol. When subjected to dry distillation, it melts and carbonises, giving off alkaline vapours, which have the odour of chinoline, and appear to consist of that alkaloïd; cyanic acid is also produced.

Trigenic acid is not precipitated by nitrate of silver unless ammonia is also added, in which case *trigenate of silver*, $C^4H^6AgN^3O^2$, is precipitated in the form of a powder, appearing under the microscope to consist of crystalline spherules; when exposed to light, it acquires a violet tint. It dissolves in boiling water, and is deposited in the pulverulent state on cooling. Between 120° and 130° it gives off water, and becomes light-brown; and at 160° it melts, turning black, and giving off a thick vapour having the odour of chinoline.

TRIGLOCHIN. *Arrow-grass.*—A genus of plants belonging to the juncaginaceous order. *Tr. maritimum* contains, according to Sprengel (J. techn. Chem. v. 293; vi. 92), in 100 pts: 76·0 water, 20·7 organic substance, and 2·24 ash (I.). *Tr. palustre* contains 75·0 per cent. water, 22·7 organic substance, and 2·12 ash (II.). The ashes of these two plants contain, in 100 pts.:

	K^2O.	Na^2O.	CaO.	MgO.	Al^2O^3.	Fe^2O^3.	Mn^2O^3.	SiO^2.	Cl.	P^2O^5.	SO^3.
I.	17·7	22·3	10·0	2·2	0·2	1·7	. .	4·4	3·28	4·9	3·8
II.	13·7	20·7	14·6	3·9	0·2	0·4	1·5	5·1	13·0	0·6	26·1

The root of *Tr. maritimum* is said to yield a large quantity of starch.

TRIGLYCOLLAMIC ACID. See GLYCOLLAMIC ACIDS (ii. 905).

TRIHEPTYLAMINE. $(C^7H^{15})^3N$.—*Triœnanthylamine.* (Petersen and Gössmann, Ann. Ch. Pharm. ci. 310; cii. 312; Jahresb. 1857, p. 388.—Petersen, Ann. Ch. Pharm. cxxxii. 158; Jahresb. 1865, p. 420.)—This base, originally regarded as trihexylamine (tricapronylamine), is produced by heating sulphite of œnanthyl-ammonium with three times its weight of a mixture of quicklime and slaked lime:

$$3(C^7H^{15})(NH^4)SO^3 + 3CaO = (C^7H^{15})^3N + 2NH^3 + 3CaSO^4.$$

It is also formed by heating œnanthyl-ammonium-sulphite by itself to 260°—270° in a sealed tube. When purified by boiling with sodic carbonate, washing with water, and rectifying in a stream of hydrogen, it forms a liquid, pale-yellow by transmitted, greenish-yellow by reflected light, and strongly efflorescent; it has an alkaline reaction, a peculiar aromatic odour, and an alkaline aromatic taste, producing afterwards a scratching sensation in the throat. It is lighter than water, and nearly insoluble therein, easily soluble in alcohol and in ether. It precipitates alumina and ferric oxide from their salts, and redissolves them in excess; does not decompose ammonia-salts.

The base turns brown on exposure to the air; its salts are all deliquescent, easily alterable, and form oily drops or syrupy masses.—The *chloroplatinate*, $2C^{21}H^{46}NCl.PtCl^4$, separates from alcoholic solution, by evaporation in a vacuum, in yellow shining scales.

The base, left in contact for several weeks with ethylic iodide, or heated with it to 100° for 24 to 48 hours, forms a red oily mass, consisting of iodide of triheptyl-ethyl-ammonium, $(C^7H^{15})^3(C^2H^5)NI$.

TRIHEPTYLIDENE-DIROSANILINE. $C^{61}H^{74}N^6 = \left.\begin{matrix}(C^{20}H^{16})^2\\(C^7H^{14})^3\end{matrix}\right\}N^6 = \left.\begin{matrix}(C^6H^4)^2\\(C^7H^6)^4\\(C^7H^{14})^3\end{matrix}\right\}N^6$.—*Triœnanthylidene-dirosaniline.* (H. Schiff, Compt. rend. lxi. 45; Jahresb. 1865, p. 420.)—Produced as an acetate, by the action of œnanthol on crystallised acetate of rosaniline at ordinary temperatures, and separated by potash, from the blue alcoholic solution of that salt, in red crystalline flocks:

$$\underset{\text{Rosaniline.}}{2(C^{20}H^{16})H^3N^3} + \underset{\text{Œnanthol.}}{3C^7H^{14}O} = \underset{\text{Triheptylidene-dirosaniline.}}{(C^{20}H^{16})^2(C^7H^{14})^3N^6} + 3H^2O.$$

It forms crystalline copper-coloured salts, insoluble in water, and several platinum-salts. Both the base and its salts decompose even below 100°, especially in presence of excess of œnanthol, yielding a yellow resinous mass, consisting mainly of heptylidene-dibenzylidene-diamine, $C^{21}H^{26}N^2 = (C^7H^{14})(C^7H^6)^2N^2$. This compound scarcely exhibits basic properties, but nevertheless forms a yellow platinum-salt, $2(C^{21}H^{26}N^2.HCl).PtCl^4$. Its formation probably takes place in the manner represented by the equation:

$$\underset{\text{Triheptylidene-dirosaniline.}}{\left.\begin{matrix}(C^6H^4)^2\\(C^7H^6)^4\\(C^7H^{14})^3\end{matrix}\right\}N^6} = \underset{\text{Heptylidene-diphenylene-diamine.}}{\left.\begin{matrix}(C^6H^4)^2\\C^7H^{14}\end{matrix}\right\}N^2} + \underset{\text{Heptylidene-dibenzylidene-diamine.}}{2\left[\left.\begin{matrix}(C^7H^6)^2\\C^7H^{14}\end{matrix}\right\}N^2\right]}.$$

TRIHYDROCARBOXYLIC ACID. See HYDROCARBOXYLIC ACIDS (iii. 189).

TRIMERCURANIL, NITRATE OF. Syn. with NITRATE OF DIPHENYLTRIMERCURAMMONIUM. (See PHENYLAMMONIUMS, iv. 475.)

TRIMETHYL-GLYCERIN, or **TRIMETHYLIN,** $C^6H^{14}O^3 = \left.\begin{matrix}(C^3H^5)'''\\(CH^3)^3\end{matrix}\right\}O^3$, is formed by heating 1 vol. acrolein, 3 vols. methylic alcohol, and 0·5 vol. acetic acid, to 100° for several hours. It is a liquid having an agreeable odour, somewhat soluble in water, boiling at 148°, and having a specific gravity of 0·9433 at 0°. (Alsberg, Jahresb. 1865, p. 495.)

TRIMETHYLSULPHINE. See the next article.

TRIMETHYLSULPHUROUS COMPOUNDS. (Cahours, Ann. Ch. Pharm. cxxxvi. 151; Jahresb. 1865, p. 476.—Dehn, Ann. Ch. Pharm. Suppl. iv. 83; Jahresb. 1865, p. 479.)—These compounds are analogous in composition to the triethylsulphurous compounds above described (p. 881), and are obtained by similar reactions.

Sulphurous Iodotrimethide, $S^{iv}\left\{\begin{matrix}(CH^3)^3\\I\end{matrix}\right.$, or *Iodide of Trimethylsulphine,* $(CH^3)^3S.I$, is produced by direct combination of methylic sulphide, $(CH^3)^2S$, and methylic iodide, CH^3I; the two substances unite, at ordinary temperatures, to a white crystalline mass, which dissolves easily in hot water, and separates, by slow evaporation, in large prisms, quickly turning brown on exposure to light. The same compound is produced, together with methylic sulphydrate, by heating methylic sulphide with hydriodic acid in a sealed tube (Cahours):

$$2(CH^3)^2S + HI = (CH^3)^3SI + CH^3.H.S.$$

A mixture of methylic sulphocyanate and methylic iodide also solidifies on cooling to a crystalline mass consisting mainly of sulphurous iodotrimethide. This compound is slightly soluble in strong alcohol, insoluble in ether, and crystallises from aqueous alcohol in white needles, made up of small rhombic tablets. The aqueous solution is partly decomposed on evaporation, yielding methylic sulphide and free iodine. (Dehn.)

The iodide, decomposed with recently-precipitated silver-oxide, yields sulphurous hydroxyltrimethide, $S^{iv}\left\{\begin{matrix}(CH^3)^3\\HO\end{matrix}\right.$, or hydrate of trimethylsulphine, $(CH^3)SHO$, which is a strongly alkaline base, and, when neutralised with hydrochloric acid, yields the corresponding chloride in colourless deliquescent prisms.—The *chloroplatinate,* $2(CH^3)^3SCl.PtCl^4$, crystallises from hot water in sparingly soluble orange-yellow prisms.—The *chloroaurate* and *chloromercurate* also crystallise distinctly. The other salts, obtained by decomposing the iodide with silver-salts, are crystallisable and deliquescent (Cahours).—The *nitrate* forms, with nitrate of silver, a sparingly soluble double salt, which crystallises in needles. (Dehn.)

Sulphurous Iodo-ethyldimethide, $S^{iv}\left\{\begin{matrix}(CH^3)^2\\C^2H^5\\I\end{matrix}\right.$, is produced by the combination of methylic sulphide with ethylic iodide. (Cahours.)

Sulphurous Dibromodimethide, $S^{iv}\left\{\begin{matrix}(CH^3)^2\\Br^2\end{matrix}\right.$, is produced by adding bromine to methylic sulphide diffused through half its bulk of water, and treating the resulting reddish-yellow crystalline compound with a few drops of methylic sulphide. It is deliquescent, and separates from its colourless aqueous solution, by evaporation in a vacuum over oil of vitriol, in amber-yellow octahedral crystals. Moist silver-oxide converts it, at ordinary temperatures, into the corresponding oxide, $S(CH^3)^2SO$, which does not exhibit any alkaline reaction. (Cahours.)

Sulphurous Dibromo-ethylene-tetramethide, $\overset{iv}{S^2}\left\{\begin{matrix}(C^2H^4)''\\(CH^3)^4\\Br^2\end{matrix}\right.$, is produced, by heating 1 at. ethylenic bromide with 2 at. methylic sulphide to 100°, as a crystalline mass, which dissolves readily in water, and crystallises in a vacuum, in colourless well-defined crystals. It is deliquescent, is dissolved in all proportions by hot water, less easily by alcohol, is insoluble in ether, and is precipitated by ether from the alcoholic solution in white prisms. With silver-salts it yields silver-bromide, and very deliquescent salts; with recently-precipitated silver-oxide, a caustic alkaline solution, containing the oxide, $\overset{iv}{S^2}\left\{\begin{matrix}(C^2H^4)''\\(CH^3)^4\\O\end{matrix}\right.$.—The *chloroplatinate,* $(C^2H^4)(CH^3)^4S^2Cl^2.PtCl^4$, is orange-yellow and crystalline. (Cahours.)

Sulphurous Tribromo-ethenylhexmethide, $\overset{''}{S}{}^{3}\left\{\begin{matrix}(CH^{3})^{6}\\(C^{2}H^{3})'''\\Br^{3}\end{matrix}\right.$, is produced by combination of 3 at. methylic sulphide, $(CH^{3})^{2}S$, with 1 at. monobromethylenic bromide, $C^{2}H^{3}Br.Br^{2}$. It is crystallisable, deliquescent, and reacts with silver-oxide like the preceding. (Cahours.)

Iodoform dissolves easily in methylic sulphide, and crystallises out unaltered, on leaving the liquid to evaporate; but the mixture, if heated to 180°, turns brown, and deposits a dark-coloured crystalline mass, analogous in composition to the bromide last decribed. (Cahours.)

TRIMETHYL-TELLUROUS COMPOUNDS. (Cahours, *loc. cit.*)—*Tellurous iodotrimethide*, $Te^{iv}\left\{\begin{matrix}(CH^{3})^{3}\\I\end{matrix}\right.$, produced by direct combination of methylic telluride with methylic iodide, is crystalline, slightly soluble in water, easily soluble in alcohol. The alkaline base, obtained from it by the action of silver-oxide, yields, when neutralised with hydrochloric acid and treated with platinic chloride, a *chloroplatinate*, $2(CH^{3})^{3}TeCl.PtCl^{4}$, isomorphous with the corresponding sulphur-compound.

Similar compounds are formed with ethylic telluride and iodide; also with the corresponding selenides and iodides.

TRIMORPHISM. See DIMORPHISM (ii. 331).

TRINACRITE. A mineral from the palagonite tufa of Cape Passaro, in Sicily, in which it occurs mixed with siderosilicite. It contains 31·82 per cent. SiO^{2}, 33·95 $Fe^{2}O^{3}$, 5·26 $Al^{2}O^{3}$, 2·52 CaO, 4·57 MgO, 4·19 $Na^{2}O$, and 3·4 $K^{2}O$. (S. v. Waltershausen, *Vulcanische Gesteine*, p. 232.)

TRIŒNANTHYLAMINE. Syn. with TRIHEPTYLAMINE (p. 884).

TRIŒNANTHYLIDENE-DIROSANILINE. Syn. with TRIHEPTYLIDENE-DIROSANILINE (p. 884).

TRIOILITE. A name applied by Haidinger to the sulphide of iron, FeS, occuring in meteorites. (Jahresb. 1863, p. 905.)

TRIOXAMYLAMINE. $(C^{5}H^{11}O)^{3}N$. (J. Erdmann, Ann. Ch. Pharm. cxxx. 211; Jahresb. 1864, p. 420.)—A base produced by heating anhydrous valeral-ammonia, or a mixture of valeral and strong aqueous ammonia, to 130° in sealed tubes for six or eight hours:

$$3(C^{5}H^{10}O.NH^{3}) \;=\; (C^{5}H^{11}O)^{3}N \;+\; 2NH^{3}.$$

Erdmann designated this base as *triamylidenoxydammonia*, or *trioxamylidene*; the name and formula above given, which represent the base as analogous to hydrobenzamide, &c., were suggested by Petersen. (Ann. Ch. Pharm. cxxxii. 158.)

To obtain the pure base, the oily layer, which floats on the liquid when the reaction is completed, is distilled with water; the non-volatile portion, separated from the water, is dissolved in strong hydrochloric acid; and the hydrochlorate, $(C^{5}H^{11}O)^{3}N.HCl$, which separates from the solution in crystalline crusts, is washed with a little water, pressed between filter-paper, recrystallised from alcohol, washed with ether, and then shaken up with ammonia and ether. The resulting solution yields the base, on evaporation, as a colourless viscid oil, having a pungent odour when warm, and a specific gravity of 0·879 at 22°. It is partially decomposed by distillation, with evolution of ammonia, has a strong alkaline reaction, is but slightly soluble in water, easily soluble in alcohol, and, when once separated, unites but slowly with acids, forming crystallisable salts.—The *chloroplatinate*, $2(C^{15}H^{33}O^{3}N.HCl).PtCl^{4}$, is resinous, and crystallises from alcohol in yellowish-red granules.

Trioxamylamine, heated for several hours with *ethylic iodide*, is partially acted on, forming an iodide, which, when treated with silver-oxide, yields a very bitter alkaline base, obtainable in the form of a soft yellowish resin.

TRIOXYALIZARIN. Syn. with PSEUDOPURPURIN. (See PURPURIN, iv. 751.)

TRIOXYPROTEIN. See PROTEIN (iv. 738).

TRIPE-STONE. A variety of anhydrous calcic sulphate, composed of contorted plates.

TRIPHANE. Syn. with SPODUMENE (p. 403).

TRIPHYLLINE. Lithio-ferroso-manganous phosphate, $(Li^{2};Fe;Mn'')^{3}P^{2}O^{8}$. (See PHOSPHATES, iv. 572.)

TRIPLE SALTS. A name sometimes applied to salts containing three different bases, such as microcosmic salt, $Na(NH^{4})HPO^{4}$.

TRIPLITE. Ferroso-manganous phosphate. (See PHOSPHATES, iv. 571.)

TRIPOCLASE. Syn. with THOMSONITE (p. 784).

TRIPOLI. *Quarz aluminifère tripoléen. Argile tripoléenne. Terra tripolitana.*—A mineral consisting chiefly of silica, with small quantities of alumina, ferric oxide, and water, occurring massive in beds and nodules in various formations. Its structure is coarsely or finely earthy, sometimes rather slaty in the mass; of whitish, yellowish, greyish to blackish colour; sometimes spotted or striped; dull; opaque; somewhat rough to the touch; soft to friable, and of specific gravity 1·86 to 2·7. It may be regarded as an earthy variety of opal.

TRITHIONIC ACID. $H^2S^3O^6$. See SULPHUR, OXYGEN-ACIDS OF (p. 639).

TRITICIN. A name sometimes applied to the gluten of wheat.

TRITICUM. A genus of grasses including wheat. The rootstock of *Tr. repens* (couch-grass) is distinguished by its sweetish taste. Pfaff found in it a peculiar sugar, which Berzelius regarded as mannite. Stenhouse (Ann. Ch. Pharm. li. 354), by exhausting the extract of the plant with alcohol, obtained no mannite, but needle-shaped crystals of acid potassic oxalate, and an uncrystallisable, easily fermentable sugar. Völcker, however (*ibid.* lix. 380), has frequently observed the occurrence of mannite in the extract of couch-grass root; he found, indeed, that the extract of roots grown in the hot and dry summer of 1849, solidified almost entirely to a mass of needles of mannite. (Handw. d. Chem. viii. 1031.)

Respecting the composition of wheat (*Tr. vulgare*, &c.), and of its ash, see CEREALS (i. 824—828).

TRITOMITE. A hydrated silicate of cerium, lanthanum, calcium, &c., occurring in the syenite of the island of Lamö, near Brevig in Norway, in imbedded tetrahedrons exhibiting no distinct cleavage, but only a conchoïdal fracture. Hardness = 5·5. Specific gravity = 3·90 to 4·66. Colour brown to yellow; streak yellowish-grey. Lustre semi-metallic. Opaque or translucent on the edges only. When heated before the blowpipe, it often splits violently, swells up, and turns white. With borax, it forms a reddish-yellow bead, becoming colourless on cooling; when heated in a tube, it gives off water and fluorine. In the pulverulent state, it dissolves in hydrochloric acid, with evolution of chlorine and separation of gelatinous silica.

TRITOXIDE. A term formerly used to denote the third in a series of oxides, the first and second terms of which were called protoxide and deutoxide. (See NOMENCLATURE, iv. 123.)

TRITYL (better known as **PROPYL**) is the third radicle of the series C^nH^{2n+1}. Existing in combination, its formula is C^3H^7. In the free state it can hardly be said to be known as an actual substance, but, in accordance with received doctrines, its formula must be C^6H^{14}, and it is probably identical with the hydride of hexyl occurring in petroleum (iii. 153).

Isotrityl, or isopropyl, differs from propyl, and has been obtained by Schorlemmer (Proc. Roy. Soc. xvi. 35), by acting on iodide of isopropyl with sodium in presence of ether. It is a colourless mobile liquid, resembling the hexyl-hydride of petroleum in smell, but having a lower boiling-point, viz. 58°. Specific gravity at 10° = 0·6769. It is easily attacked by chlorine in the cold, yielding $C^6H^{13}Cl$. With chlorine and iodine it gives, not $C^6H^{13}Cl$, but $C^6H^{12}Cl^2$, and products still more highly chlorinated. Dilute chromic acid oxidises it to acetic and carbonic acids.

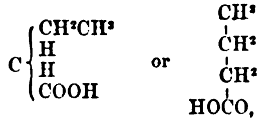
Isopropyl combines with alcohol-radicles when it is liberated nascent, in presence of the radicles also in the nascent state. Thus Schorlemmer (*loc. cit.*) obtained amylisopropyl, C^8H^{18}, a colourless liquid, boiling at 109°—110°, and of specific gravity 0·6980 at 16·5°, by attacking a mixture of iodide of amyl and iodide of isopropyl with sodium.

The difference in structure between normal trityl and isotrityl is expressed by the following formulæ:

Compound of normal trityl.	Compound of isotrityl.
$C\left\{\begin{array}{l}CH^2CH^3\\H\\H\\R\end{array}\right.$	$C\left\{\begin{array}{l}CH^3\\CH^3\\H\\R\end{array}\right.$

(See SECONDARY ALCOHOLS, p. 215). Our knowledge of the entire trityl-group is very imperfect, and, for the most part, of very recent date.

Of normal trityl-compounds we know common butyric acid, which is



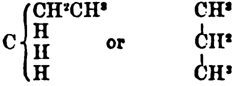
$$C\left\{\begin{array}{l}CH^2CH^3\\H\\H\\COOH\end{array}\right.\quad\text{or}\quad\begin{array}{c}CH^3\\|\\CH^2\\|\\CH^2\\|\\HOCO,\end{array}$$

being "propylated" acetic acid, or, what is the same thing, a compound of normal propyl with oxatyl (O = C-OH)'. (Frankland and Duppa.)

Propylamine, obtained by Mendius, who treated cyanide of ethyl with nascent hydrogen, is a normal trityl-compound, giving, as Chapman and Thorp have shown, propione-aldehyde and propionic acid when subjected to the process of "limited oxidation."

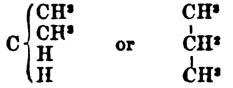
Hydride of propyl must belong to both the normal and the iso-series, as is obvious on inspection of the formulæ:

Normal propylic hydride.



$$C\left\{\begin{array}{l}CH^2CH^3\\H\\H\\H\end{array}\right.\quad\text{or}\quad\begin{array}{c}CH^3\\|\\CH^2\\|\\CH^3\end{array}$$

Isopropylic hydride.



$$C\left\{\begin{array}{l}CH^3\\CH^3\\H\\H\end{array}\right.\quad\text{or}\quad\begin{array}{c}CH^3\\|\\CH^2\\|\\CH^3\end{array}$$

In both normal- and iso-hydride of propyl, there is an atom of carbon which is directly united with two atoms of hydrogen and with two equivalents of carbon belonging to separate atoms of carbon.*

With the exception of butyric acid and its derivatives, propylamine and its derivatives, cyanide of propyl and propyl-hydride, wherein the two series become fused together, there is at the present date (1867) no known compound which can be said with certainty to contain normal propyl. Whether a numerous set of normal propyl-compounds is inherently impossible, or only not discovered, remains to be seen.

One of the earliest (if not the earliest) recognitions of the trityl-group is to be found in Chancel's note in the Comptes Rendus, xxxvii. 410 (1853), which describes a trityl-alcohol extracted by fractional distillation from large quantities of crude amylic alcohol. Great uncertainty surrounds this research of Chancel's, which requires confirmation by the much-improved methods of later years, before we can receive it as an established fact that some varieties of fusel-oil contain tritylic alcohol.

Attempts to form normal trityl-alcohol by synthesis have hitherto failed. Attempts have been made to produce it by means of propylamine, prepared by the method of Mendius from cyanide of ethyl and nascent hydrogen. Nitrous acid attacks the propylamine, but no modification of the method of experimenting has yet succeeded in converting the propylamine into the normal alcohol. The attempt to make it through the aldehyde— which, if Williamson's reaction were of general application, should be formed by the distillation of a mixture of propionate and formate of barium—has miscarried even earlier in the process, for, according to recent researches, propione-aldehyde itself fails to be formed.

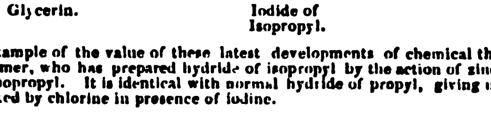
It yet remains to try to add hydrogen to the normal propione-aldehyde obtained by the oxidation of Mendius's propylamine, or to chlorinate the hydride of propyl, and then proceed, through the resulting chlorine-compound, to the acetic ether and alcohol.

Isopropyl-compounds are, on the other hand, obtained with facility, and in a perfectly satisfactory condition.

Berthelot has shown that propylene, the olefine of the group, is easily hydrated by means of acids:

$$\underset{\text{Propylene.}}{C^3H^6} + H^2O = \underset{\text{Isopropyl-alcohol.}}{C^3H^8O.}$$

Erlenmeyer has transformed glycerin into iodide of isopropyl, which is capable of giving the isoalcohol:



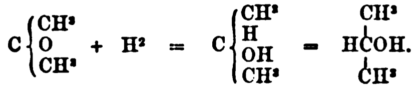
$$\left\{\begin{array}{c}H^2COH\\|\\HCOH\\|\\H^2COH\end{array}\right. + 5HI = \begin{array}{c}H^2CH\\|\\HCI\\|\\H^2CH\end{array} + 3H^2O + 2I^2.$$

Glycerin. Iodide of Isopropyl.

---

* A striking example of the value of these latest developments of chemical theory has just been given by Schorlemmer, who has prepared hydride of isopropyl by the action of zinc and hydrochloric acid on iodide of isopropyl. It is identical with normal hydride of propyl, giving normal chloride of propyl when attacked by chlorine in presence of iodine.

Finally, Friedel has added hydrogen to acetone, and produced the iso-alcohol. This important reaction completely clears up the structure of the isopropyl-compounds:



$$C\left\{\begin{array}{l}CH^3\\O\\CH^3\end{array}\right. + H^2 = C\left\{\begin{array}{l}CH^3\\H\\OH\\CH^3\end{array}\right. = \begin{array}{c}CH^3\\|\\HCOH.\\|\\CH^3\end{array}$$

Acetone. Isopropyl-alcohol.

(See SECONDARY ALCOHOLS, p. 215.) J. A. W.

TRITYL ALCOHOLS. Normal trityl alcohol is not known with certainty. It is said to boil at 96° to 97°, and to be a fruity liquid, very soluble in water, but not soluble in all proportions, and to be contained in some samples of crude amylic alcohol. (Chancel, Compt. rend. [1853] xxxvii. 410.)

A tritylsulphuric acid, formed by the action of sulphuric acid on the alcohol, is also described.

Isotrityl alcohol, or *Isopropyl alcohol*, or *Pseudopropyl alcohol*, or *Propylene-hydrate.*—Formed, as just described, from propylene, glycerin, or acetone.

Preparation.—α. From Oxalate, or Acetate of Isopropyl, which may be easily decomposed by potash or soda. If the alcohol is wanted in large quantities, this would probably prove the most convenient process, inasmuch as the iodide of isopropyl, from which the oxalate or acetate may be readily prepared, is easily obtained pure and in large quantity.

β. From Acetone.—One vol. of acetone is added to 5 vols. of water, and then treated with sodium-amalgam. After a while, an oily layer separates. The whole liquid is then to be distilled, and the oily distillate mixed with water, and again treated with sodium-amalgam. By repeating this process six times, a transformation of much of the acetone into the isoalcohol is effected. In order to purify the product, it is dried with carbonate of potassium and distilled, then rubbed up with powdered and well-dried chloride of calcium. The mass is subsequently dried in a vacuum over sulphuric acid, when the acetone evaporates, leaving a dry powder, consisting of the compound of isoalcohol with chloride of calcium. Simple heating drives off the isoalcohol from this compound, and rectification suffices to purify it completely. (Linnemann, Ann. Ch. Pharm. cxxxvi. 37.)

Properties.—Isopropyl alcohol is a colourless, not very mobile liquid, having a peculiar odour, not at all resembling that of amyl alcohol. Boils at 83°—84°, under a pressure of 739 mm. At 15°, its specific gravity is 0·791. It does not freeze at −20°. It does not act on polarised light. It is very difficult to dry, mixing with water in all proportions, and forming several hydrates of considerable stability. The existence of these hydrates was first observed by Erlenmeyer, and afterwards confirmed by Linnemann. The following is the composition of these hydrates:

I. ($3C^3H^8O.2H^2O$) boils at 78°—80°; specific gravity, 0·832 at 15°.
II. ($2C^3H^8O.H^2O$) „ 80°
III. ($3C^3H^8O.H^2O$) „ 81°; specific gravity, 0·800 at 15°.

The second, discovered by Erlenmeyer, simulates common alcohol, having exactly the same percentage composition as that substance. It boils only slightly higher than common alcohol, and retains water so strongly, that it does not render blue the white anhydrous sulphate of copper. In order to dehydrate it completely, it is well to use a little metallic sodium. To distinguish between this hydrate and common ethylic alcohol, the readiest plan is to submit the liquid to the action of *iodine* and *phosphorus*, which transforms the one into iodide of isopropyl, and the other into iodide of ethyl. The resemblance extends very far. Both compounds yield acetic acid on *oxidation*, the hydrate of isopropyl alcohol giving, however, carbonic acid in addition.

The characteristic property of isopropyl alcohol is, that it yields acetone by oxidation with dilute chromic acid. This important observation was made by Friedel, after it had been predicted, in a most remarkable manner, by Kolbe, who had had, so to speak, a vision of the secondary alcohols with their leading characteristics. On pushing the oxidation further, the acetone breaks up into acetic acid, carbonic anhydride, and water:

$$C\left\{\begin{array}{l}CH^3\\CH^3\\H\\OH\end{array}\right. + O = C\left\{\begin{array}{l}CH^3\\CH^3\\O\end{array}\right. + H^2O.$$

Isopropyl alcohol. Acetone.

$$C\left\{\begin{array}{l}CH^3\\CH^3\\O\end{array}\right. + O^4 = C\left\{\begin{array}{l}CH^3\\O\\OH\end{array}\right. + CO^2 + H^2O.$$

Acetone. Acetic acid.

Bromine attacks isopropyl alcohol, withdrawing hydrogen, and leaving acetone. In practice, this reaction is very complicated, the hydrobromic acid resulting from this change attacking some of the isoalcohol, and giving bromide of isopropyl, and the acetone suffering a further attack.—Distilled with *acetate of potassium* and *sulphuric acid*, it yields acetate of isopropyl.—Digestion at 140° with *acetic acid* also gives the acetate of isopropyl. The butyric ether is formed similarly, and distils at about 130°.

J. A. W.

TRITYL ETHERS. The normal trityl ethers are scarcely known, but several isotrityl ethers have been prepared:—

Bromide of Isopropyl, C^3H^7Br, is obtained by heating the alcohol with hydrobromic acid, also by the action of bromine on the iodide of isopropyl. It is a liquid. Specific gravity = 1·320 at 13°. Boiling-point = 60° to 63° at 739 mm. pressure.

Chloride of Isopropyl, C^3H^7Cl, prepared by the action of hydrochloric acid on the alcohol, is a liquid, boiling at 36° to 38°, at 741 mm. pressure. Specific gravity at 10° = 0·874.

Cyanide of Trityl, $C^3H^7.CN$. (See BUTYRONITRILE, i. 698.)—This compound is obtained from normal butyric acid, and yields normal butyric acid and ammonia when it is made to take up water.

Cyanide of Isopropyl, C^3H^7CN. (Erlenmeyer.)—When 1 at. iodide of isopropyl and 1 at. cyanide of potassium, dissolved in alcohol, are digested in the water-bath, iodide of potassium is formed, the liquid acquires a very disagreeable smell, and there results an alcoholic solution of cyanide of isopropyl. It is difficult to separate the alcohol from the cyanide, which boils at about 80°. On boiling cyanide of isopropyl with alcoholic potash, ammonia is evolved, and isobutyrate of potassium produced:

$$C^3H^7CN + 2H^2O = C^3H^7COOH + NH^3.$$

Isobutyric acid is quite distinct from butyric acid, and was the first recognised example of an iso-fatty acid.

Iodide of Isopropyl, C^3H^7I. (Erlenmeyer, Zeitschr. Ch. Pharm. 1861, pp. 362, 673.)—Obtained by the action of hydriodic acid on propylglycol, iodide of allyl, isopropyl alcohol, propylene, or glycerin. It is most conveniently prepared by distilling glycerin with a great excess of strong hydriodic acid:

$$C^3H^8O^3 + 5HI = C^3H^7I + 3H^2O + 2I^2.$$

The reaction is perfectly neat, if proper precautions be taken. The conditions to be satisfied are these:—The hydriodic acid used must be sufficiently strong (boiling-point about 125°); if too dilute it may be concentrated by distillation, the strong acid remaining behind in the retort. There must be always great excess of hydriodic acid. The iodine set free should be reconverted into hydriodic acid by means of phosphorus. The operation succeeds either on the small or the large scale. The iodide of isopropyl has been recently manufactured in quantity.

Preparation.—100 lbs. of iodine, 5 lbs. of phosphorus, and 100 lbs. (or rather more) water, are employed. A little of the water is warmed, and put into a large vessel; and the iodine and phosphorus and water are added by degrees, and well stirred up. The stirring renders the reaction quite manageable. The first quantity of water is warmed to start the reaction, afterwards the water is added cold. In this way there is obtained a strong solution of hydriodic acid containing also some phosphoric acid. This solution is put into an iron still and distilled, until very concentrated hydriodic acid begins to pass over. When the concentration is sufficient, a charge of 11 lbs. of glycerin is put into the still, and 3 lbs. of phosphorus added by degrees. A very energetic action is thus set up, and iodide of isopropyl distils over very rapidly, accompanied by water and hydriodic acid. When the action has become moderate, a second charge of 11 lbs. of glycerin and 3 lbs. of phosphorus is introduced into the still. When the second charge has worked off, a small third charge may be put in.

Ultimately the products are iodide of isopropyl, hydriodic acid, and phosphoric acid. When the phosphoric acid has accumulated, it is necessary to distil off. The hydriodic acid is ready for a second operation. By operating as above described, a quantity of iodide of isopropyl may be obtained, very close upon that required by theory, and in a series of operations very nearly all the iodine used may be transformed into the organic iodide.

The iodine, as it is set free, is transformed into hydriodic acid by the action of the phosphorus and water, and becomes available.

If an insufficient quantity of hydriodic acid be allowed to act on the glycerin in the above process, the iodide of isopropyl will be contaminated with iodide of allyl.

Maxwell Simpson has shown that iodide of allyl is transformed into iodide of isopropyl by treatment with hydriodic acid.

Properties.—Iodide of isopropyl is an oil, boiling at 89° to 90°, under a pressure of 735 mm. Specific gravity 1·70 at 15°. In smell it resembles iodide of ethyl. It is nearly insoluble in water, and dissolves phosphorus and iodine.

With *sodium*, in presence of ether, it gives propylene, hydride of propyl, and di-isopropyl (Schorlemmer).—*Bromine* drives out the iodine, forming a bromide of the radicle.—*Chlorine* attacks it more deeply, giving, among other products, trichlorhydrin, $C^3H^5Cl^3$.—With *oxalate of silver*, it gives oxalate of isopropyl.—With *acetate of silver*, it yields acetate of isopropyl, boiling at 90°—93°, according to Friedel.

With *oxide of silver* and *water*, it gives isopropyl ether, $\left.\begin{matrix} C^3H^7 \\ C^3H^7 \end{matrix}\right\} O$, isopropyl alcohol, and propylene, C^3H^6.

With *alcoholic potash* it gives propylene. It reacts on *ammonia*, giving some propylene and an organic base. It forms new bases when made to act on *aniline* or on *rosaniline*.

Carefully oxidised with dilute *chromic acid*, it gives acetic and carbonic acids, and no propionic acid. (Chapman and Thorp.) J. A. W.

TRITYL, HYDRIDE OF. This compound appears to occur in American petroleum (Ronalds). By heating to 275° a mixture of bromide of propylene, $C^3H^6Br^2$, iodide of potassium, and water, with metallic copper, there is obtained propylene, hydride of propyl, and carbonic acid. Hydride of propyl is a gas, which is soluble in alcohol. J. A. W.

TRITYLAMINE, or **PROPYLAMINE.** $N\left\{\begin{matrix} C^3H^7 \\ H \\ H \end{matrix}\right.$.—This base is isomeric with trimethylamine, which has often been mistaken for it. The only process by which it has been prepared is that of Mendius, viz., by the hydrogenation of cyanide of ethyl:

$$C^2H^5CN + H^4 = C^3H^9N.$$

To prepare propylamine, 36 grms. of cyanide of ethyl, 500 grms. of common alcohol, 200 grms. of water, and 500 grms. of 20 per cent. hydrochloric acid, are allowed to act on excess of granulated zinc, and then distilled. The distillate is put back once, and 400 grms. of hydrochloric acid are added. The product is distilled to get rid of the alcohol, then excess of alkali added to the residue, and the distillation continued, whereupon propylamine and water come over.

From 36 grms. of the cyanide of ethyl, 9 grms. of pure propylamine have been obtained (Mendius). Propylamine is dried by distillation from solid potash.

Properties.—Bright, colourless, highly refracting, very mobile liquid, possessing a peculiar, strongly ammoniacal odour, very different from that of methylamine. It is miscible with water, becoming hot in contact with it. Boils at 50°. Its aqueous solution precipitates the oxides of iron, copper, lead, aluminium, nickel, cobalt, and mercury, and does not dissolve the precipitate when added in excess.

The precipitate formed with silver-solutions is soluble in excess.

The propylamine, prepared as just described, is a true normal propyl-compound, giving, on oxidation with dilute chromic acid, propione-aldehyde and propionic acid, and not giving any carbonic acid or acetic acid. (Chapman and Thorp.)

It combines with acids, forming crystallisable salts.—The *chloride*, NC^3H^9HCl, forms very deliquescent crystals, freely soluble in alcohol, almost insoluble in ether. A little above 100° it melts, and sublimes unchanged. It may be obtained, in large square plates, by crystallisation from strong alcohol.—The *chloroplatinate*, $2NC^3H^{10}Cl.PtCl^4$, is moderately soluble in hot water and alcohol, and insoluble in ether. It often forms fine crystals, a quarter of an inch long.

Sulphate of propylamine is crystalline and deliquescent.

On treating propylamine with *iodide of ethyl*, the following products are obtained:

$$\begin{matrix} N\left\{\begin{matrix} C^3H^7 \\ C^2H^5 \\ H \end{matrix}\right. & \qquad N\left\{\begin{matrix} C^3H^7 \\ C^2H^5 \\ C^2H^5 \end{matrix}\right. & \qquad N\left\{\begin{matrix} C^3H^7 \\ C^2H^5 \\ C^2H^5 \end{matrix}\right. . \\ HI & \qquad HI & \qquad C^2H^5I. \end{matrix}$$

The last compound, *iodide of triethyl-propylammonium*, is a white crystalline mass, insoluble in potash-ley. From its alcoholic solution it crystallises in long needles.

Oxide of silver reacts upon it, giving a strongly caustic solution of hydrate of the ammonium-base.—The *chloroplatinate*, $2NC^3H^7(C^2H^5)^3Cl.PtCl^4$, forms deep orange-coloured octahedrons, rather soluble in alcohol and water. (Mendius, Ann. Ch. Pharm. cxxi. 129.) J. A. W.

TRITYLENE, or **PROPYLENE,** C^3H^6, the olefine of the trityl-group, was discovered by Reynolds in 1851. It is obtained, more or less impure, when fusel-oil or valerianic acid is passed through a red-hot tube; by the destructive distillation of oleic acid with lime or soda-lime; and by the destructive distillation of sugar mixed with an equal weight of soda-lime. According to Dusart (Ann. Ch. Pharm. xcvii. 127), it is obtained on distilling an intimate mixture of equivalent quantities of oxalate of calcium and acetate of potassium.

It is prepared most conveniently by acting on iodide of allyl with mercury and strong hydrochloric acid. The mercury should contain a trace of zinc, according to the observation of von Than. The following are the details of the process:—

Iodide of phosphorus is prepared by acting on 1 pt. of phosphorus with 8 pts. of iodine. 50 grms. of this iodide of phosphorus, and 50 grms. of glycerin, distilled together, yield 30 grms. of iodide of allyl. From this quantity of the iodide, 3 litres of propylene may be obtained by employing 150 grms. of mercury and 50 grms. of fuming hydrochloric acid. The gas obtained in this operation is chemically pure propylene. (Berthelot and De Luca, Ann. Ch. Pharm. xcii. 306.)

According to Rieth and Beilstein, chloride of carbon, acted upon by zinc-ethyl, yields a mixture of propylene, ethylene, and chloride of ethyl, also chloride of zinc. Iodide of isopropyl and alcoholic potash also give propylene.

Properties.—Colourless gas, not condensable at – 140°. It has a distinct phosphoric odour, as is generally the case with the olefines, and a sweetish taste. According to von Than:

100 vols. of water	absorb	44	vols. of propylene	at	0°.
"	"	35	"	"	5°.
"	"	28	"	"	10°.
"	"	23	"	"	15°.
"	"	22	"	"	20°.

Absolute alcohol dissolves 12 to 15 times its volume of this gas—glacial acetic acid 6 volumes.

Like ethylene, it combines readily with *chlorine* and *bromine*, and is capable of uniting with *iodine*; the resulting compounds are $C^3H^6Cl^2$, $C^3H^6Br^2$, $C^3H^6I^2$.

It is absorbed by *cuprous chloride*, but not to the same extent as ethylene.—*Fuming sulphuric acid* absorbs it very readily.—Common *oil of vitriol*, *hydrochloric*, *hydrobromic*, and *hydriodic acids* combine with it far more readily than with ethylene. These acids convert it into isopropyl-compounds.—On oxidation with dilute *chromic acid*, it gives acetic and carbonic acids. It is not very readily oxidised.—With *permanganate of potassium* in an acid liquid, it gives the same products as with chromic acid; with permanganate in an alkaline liquid, acetic and formic acids. J. A. W.

TRITYLENIC ALCOHOL. $C^3H^8O^2 = \left.\begin{matrix}(C^3H^6)''\\H^2\end{matrix}\right\}O^2$. *Trityl, or Propylglycol.* —Prepared from the tritylenic acetate just described, by distillation with caustic potash, in the oil-bath. It is a colourless oily liquid, sweet to the taste, soluble in water and alcohol in all proportions, and soluble in 12 to 13 pts. of ether. Its specific gravity at 0° is 1·051. Boiling-point 188° to 189°.

Platinum-black oxidises it to lactic acid:

$$\underset{\text{Tritylenic hydrate.}}{C^3H^8O^2 + O^2} = \underset{\text{Lactic acid.}}{C^3H^6O^3} + H^2O.$$

Digested at 100° for some hours with strong *hydriodic acid*, it gives iodide of isopropyl (Wurtz):

$$C^3H^8O^2 + 3HI = C^3H^7I + 2H^2O + I^2.$$

With *pentachloride of phosphorus* it gives chloride of propylene, $C^3H^6Cl^2$.

Heated with dilute *nitric acid*, it is broken up into glycollic acid, whilst concentrated nitric acid resolves it into oxalic acid. J. A. W.

TRITYLENIC ETHERS. The *acetate*, $C^7H^{12}O^4 = \left.\begin{matrix}C^3H^6\\(C^2H^3O)^2\end{matrix}\right\}O^2$, was discovered by Wurtz. 320 grms. acetate of silver, 192 grms. bromide of propylene, and sufficient glacial acetic acid to bring the mixture into a semifluid state, are heated in the water-bath for four days, then mixed with ether and filtered, and the filtrate is distilled. The acetate is a colourless neutral liquid, soluble in 10 pts. of water, and boiling at 186°. Its specific gravity at 0° = 1·109.

The *bromide*, $C^3H^6Br^2$, formed directly from propylene and bromine, is a colourless oily liquid. Specific gravity = 1·974. Boiling-point 144°. It is a convenient compound for the preparation of proplylene-derivatives.

The *chloride*, $C^3H^6Cl^2$, is a liquid boiling at 103°. Specific gravity = 1·151.

The *cyanide*, $C^3H^6(CN)^2$, was discovered by Maxwell Simpson. 1 at. tritylenic bromide and 2 at. cyanide of potassium are heated with a large quantity of alcohol to 100° for about 16 hours. The product is then filtered, and deprived of alcohol by evaporation. The residue is treated with ether, and the ethereal solution evaporated to get rid of the ether, and then distilled. In this way tritylenic cyanide is obtained as a liquid, boiling between 277° and 290°. It is soluble in water, alcohol, and ether.

Heated with 1½ vols. of strong *hydrochloric acid* to 100°, it suffers a very interesting change, yielding pyrotartaric acid. In order to extract this acid, the residue, after the reaction, is treated with absolute alcohol, which dissolves the acid; the alcoholic solution is evaporated. to drive off the alcohol; and the residue crystallised from aqueous solution, and finally dissolved in ether, which on evaporation leaves the pyrotartaric acid in a state of purity:

$$\underset{\substack{\text{Cyanide of}\\\text{propylene.}}}{C^3H^6(NC)^2} + 4H^2O = \underset{\substack{\text{Pyrotartaric}\\\text{acid.}}}{C^5H^8O^4} + 2NH^3.$$

The *iodide*, $C^3H^6I^2$, is a liquid which does not solidify at −10°. It was discovered by Berthelot and De Luca (Ann. Ch. Pharm. xcii. 311). Prepared by exposing iodine in contact with propylene to sunlight, or by heating it to 50° or 60°. The resulting liquid is freed from excess of iodine by treatment with potash. It is decomposed by alcoholic potash into propylene and other products.

The *sulphide*, $C^3H^6S^2$, is a white amorphous powder, obtained by the action of tritylenic bromide on an alcoholic solution of sulphide of sodium.

The *sulphocarbonate*, $C^3H^6CS^3$, is easily obtained from an alcoholic solution of sulphocarbonate of sodium and tritylenic bromide. It is a thick liquid of disagreeable smell, and of a yellowish-brown colour. Specific gravity = 1·31 at 20°. It may be distilled in a stream of hydrogen. J. A. W.

TRITYLPHYCITE or **PROPYLPHYCITE.** $C^3H^8O^4 = \left.\begin{matrix}(C^3H^4)^{iv}\\H^4\end{matrix}\right\}O^4 = (C^3H^4)^{iv}(HO^4)$. *Glycerylenic Alcohol.*—A tetratomic alcohol, homologous, at least in composition, with phycite or erythromannite, $C^4H^{10}O^4$ (ii. 504; iv. 633). The corresponding dichlorhydrin, $(C^3H^4)Cl^2(HO)^2$, is produced by addition of hypochlorous acid to ordinary glyceric epichlorhydrin (i. 894):

$$(C^3H^5)'''\left\{\begin{matrix}Cl\\O\end{matrix}\right. + ClHO = (C^3H^4)^{iv}\left\{\begin{matrix}Cl^2\\(HO)^2\end{matrix}\right.;$$

and from this compound, the alcohol is obtained by the action of aqueous alkalis:

$$(C^3H^4)Cl^2(HO)^2 + 2KHO = (C^3H^4)^{iv}(HO)^4 + 2KCl.$$

To prepare propylphycite, the dichlorhydrin just mentioned, or the corresponding dichlorobromhydrin (p. 894), dissolved in 3 vols. alcohol, is mixed with 10 vols. water, and gradually with an excess of finely-divided hydrate of barium suspended in water, the liquid being ultimately warmed till it becomes inodorous. The baryta is then carefully precipitated with sulphuric acid; the filtrate is exactly neutralised with carbonate of lead; the dissolved lead removed by sulphydric acid; the chlorine by careful addition of silver-carbonate; any silver still remaining dissolved by sulphydric acid; and the solution, which is generally colourless (if not, it must be decolorised with animal charcoal), is evaporated over the water-bath. The residue, after being redissolved and evaporated, consists of pure propylphycite. If, however, the dichlorhydrin used in the preparation is not free from ordinary glyceric dichlorhydrin, the product will be contaminated with glycerin. In this case, the solution, freed from barium and chlorine, must be precipitated with basic lead-acetate not added in excess, and the washed precipitate, $C^3H^4.H^2Pb''O^4$, decomposed by sulphydric acid.

Propylphycite is a colourless, solid, amorphous mass,* which, on exposure to the air, quickly deliquesces to a glutinous liquid. It has a sweetish taste, is easily soluble in alcohol, does not decompose at 150°, and, if carefully heated, volatilises with only partial decomposition. In its chemical relations it resembles phycite, $C^4H^{10}O^4$. Like the sugars, it is very easily altered by acids, alkalis, and oxidising agents. On evaporating it with dilute acids or bases, it turns brown, and a humus-like body is separated.

---

* In removing the chlorine with silver-chloride, or the chlorine and barium by silver-sulphate, a crystalline substance was obtained, nearly related to propylphycite, and perhaps containing $C^3H^6O^4$. (Carius.)

With cupric oxide and potash, it forms a blue solution, which does not deposit cuprous oxide on boiling, even if the propylphycite has previously been treated with dilute sulphuric acid. From a neutral silver-solution, it reduces the metal at the boiling heat; from an ammoniacal solution, even at ordinary temperatures.

Propylphycite contains four atoms of hydrogen replaceable by metals or other radicles, two of them apparently with greater facility than the other two. In concentrated solution it takes up lime, baryta, lead-oxide, and even lead- or silver-carbonate. The solution containing lime, baryta, or lead-oxide yields, with alcohol, white bulky precipitates, soluble in water, and decomposible by carbonic acid. The lead-compound, in aqueous solution, is not completely decomposed by sulphydric acid, the filtrate still giving a precipitate with sulphide of ammonium. The compound formed on adding basic acetate of lead to a solution of propylphycite, is a bulky precipitate, soon becoming granular, and containing $C^3H^4.H^2Pb''O^4$.

Nitropropylphycite, $C^3H^4.H^2(NO^2)O^4$, is formed by dropping a scarcely liquid solution of propylphycite into cooled fuming nitric acid, and separates, on pouring the liquid into water, as a colourless viscid mass, nearly insoluble in water, but soluble in alcohol and ether. The nitro-compound becomes mobile at 100°, distils for the most part without decomposition, if carefully heated, but when quickly heated, decomposes suddenly, though without explosion. Zinc and hydrochloric acid, added to its alcoholic solution, produce chloride of ammonium and propylphycite.

TRITYLPHYCITIC or **PROPYLPHYCITIC ACID.** $C^3H^6O^5 = \left.\begin{matrix}(C^3H^2O)^{iv}\\ H^4\end{matrix}\right\}O^4$. (Carius, *loc. cit.*)—Produced by dissolving propylphycite in nitric acid of specific gravity 1·2, diluted with an equal volume of water, repeatedly evaporating the solution, neutralising with carbonate of barium, filtering from oxalate of barium, and precipitating the concentrated filtrate with alcohol. The acid, separated from the barium-salt by sulphuric acid, is a colourless, amorphous, strongly acid, deliquescent mass, which decomposes at 160°, either in the free state or combined with bases, yielding oxalic, acetic, and perhaps also glycollic acid.

The propylphycitates, excepting the lead- and silver-salts, are easily soluble; the *silver-salt* is very quickly reduced in ammoniacal solution.—The *acid barium-salt*, $C^6H^{10}Ba''O^{10} = C^3H^4Ba''O^5.C^3H^6O^5$, is an indistinctly crystalline powder.—The *acid calcium-salt*, $C^6H^{10}Ca''O^{10} = C^3H^4Ca''.O^5.C^3H^6O^5$, is not crystallisable, but is precipitated by alcohol from its aqueous solution in flocks.—The *acid lead-salt*, $C^6H^{10}Pb''O = C^3H^4Pb''O^5.C^3H^6O^5$, precipitated by neutral lead-acetate, is flocculent at first, but afterwards changes to a crystalline powder, composed of microscopic prisms.—The *normal lead-salt*, $C^3H^2Pb^2O^4$, precipitated by basic lead-acetate, is an amorphous powder.

TRITYLPHYCITIC or **PROPYLPHYCITIC DICHLORHYDRIN.** $C^3H^6Cl^2O^2 = C^3H^4.Cl^2(HO^2)$. *Glycerylenic Dichlorhydroxylate.* (Carius, *loc. cit.*)—This compound is formed, as already stated (p. 893), by addition of hypochlorous acid to glyceric epichlorhydrin.

To prepare it, epichlorhydrin is added in the dark, and with frequent agitation, to a cooled solution of hypochlorous acid (prepared by passing chlorine-gas into water in which mercuric oxide is suspended, and containing from 6 to 8 per cent. of the acid), till the odour becomes barely perceptible; the solution, filtered from mercuric oxychloride and diluted, is immediately treated with sulphydric acid gas, till the excess of hypochlorous acid is decomposed and the mercury is precipitated; the filtrate is then saturated with common salt; and the dichlorhydrin, already partly separated as an oily liquid, is further extracted by agitation with ether, and purified, after evaporation of the ether, by heating it to 160°—170° in a stream of dry carbonic anhydride, whereby any glyceric dichlorhydrin formed at the same time is decomposed.

Propylphycitic dichlorhydrin, thus obtained, is a liquid, rather mobile when warm, but of the consistence of glycerin at ordinary temperatures; it is heavier than water, has a somewhat rancid odour, dissolves easily in alcohol and in ether, but is nearly insoluble in salt-water. When heated above 200°, it decomposes, giving off hydrochloric acid, and vapours smelling of acrolein. By potash in aqueous solution, it is easily converted into propylphycite:

$$C^3H^4\left\{\begin{matrix}Cl^2\\ (HO)^2\end{matrix}\right. + 2KHO = \left.\begin{matrix}C^3H^4\\ H^4\end{matrix}\right\}O^4 + 2KCl.$$

TRITYLPHYCITIC or **PROPYLPHYCITIC DICHLOROBROMHYDRIN**, $C^3H^4\left\{\begin{matrix}Cl^2Br\\ HO\end{matrix}\right.$, is produced by heating 1 at. of the dichlorhydrin to 120°, in sealed tubes, with 1 at. dry bromine. It is a mobile liquid, having a sharp odour, decomposing at 160°, insoluble in water, but decomposed by it, with separation of bromine and hydrochloric acid. With alkalis, it reacts like the dichlorhydrin. (Carius.)

TRITYLPHYCITIC or **PROPYLPHYCITIC ETHERS.** (Carius, *loc. cit.*) —*Diaceto-propylphycite*, $C^3H^4.H^2(C^2H^3O)^2O^4$, is obtained by heating the dichlorhydrin to 100° with sodic acetate and glacial acetic acid, neutralising with sodic carbonate, and exhausting with ether. It is a viscid bitter liquid, easily soluble in water, not capable of being distilled without decomposition. Baryta decomposes it into acetic acid and propylphycite.

Triethylpropylphycite, $C^3H^4.H(C^2H^5)^3O^4$, is produced by gradually mixing an alcoholic solution of the dichlorobromhydrin with diluted and cooled sodium-ethylate, or by heating it to 150° with absolute alcohol. It is a colourless, faintly smelling lipuid, easily soluble in water and in potash-ley, heavier than water, and dissolving calcium-chloride in considerable quantity. Boiling-point = 192·8° at 0·758 met. Vapour-density, obs. = 6·65; calc. = 6·79.

Tetrethylpropylphycite, $C^3H^4(C^2H^5)^4O^4$, is produced, as shown by the equation:

$$\left.\begin{matrix}C^3H^4\\(C^2H^5)^3Na\end{matrix}\right\}O^4 + C^2H^5I = NaI + \left.\begin{matrix}C^3H^4\\(C^2H^5)^4\end{matrix}\right\}O^4,$$

by warming the triethylic ether with sodium as long as hydrogen is thereby evolved, and distilling the resulting sodium-compound with an equivalent quantity of ethylic iodide. It is a rather mobile colourless liquid, which boils between 150° and 160°, and exhibits, more plainly than the preceding compound, the odour of sugar heated above its melting-point.

Diaceto-diethylpropylphycite, $C^3H^4(C^2H^3O)^2(C^2H^5)^2O^4$, is formed, together with ethylic acetate, by heating triethylpropylphycite to 150° for several hours, with 3 vols. glacial acetic acid. It is a thick colourless liquid, which boils at about 210°, and is decomposed by baryta-water into barium-acetate, and a liquid compound soluble in water, probably consisting of diethylpropylphycite.

TROMBOLITE. Syn. with THROMBOLITE (p. 788).

TRONA. Native tetrasodic carbonate, or sesquicarbonate, $2Na^2O.H^2O.3CO^2.2aq.$ (See CARBONATES, i. 796.)

TROOSTITE. A silicate of manganese and zinc, from Sterling, in New Jersey (p. 254).

TROPÆOLIC ACID. See the next article.

TROPÆOLUM. The common nasturtium, *Tropæolum majus*, contains in 100 pts., besides the ordinary plant-constituents, 2·1 pts. volatile oil, 8·6 lime, 2·3 silica, and 0·9 of a peculiar acid called tropæolic acid. The volatile oil and the tropæolic acid are found in the entire plant, especially in the fruit and seed-coatings. The volatile oil has a peculiar odour, a sharp burning taste, and reddens the skin.

Tropæolic acid is extracted from the herb or the seed with alcohol; and on boiling the solution with water, and evaporating the filtrate, the acid crystallises in slender needles. It is white, reddens litmus strongly, and forms crystallisable salts with potash and soda (Müller, Ann. Ch. Pharm. xxv. 208). Whether this body is really a peculiar acid, further investigation must decide. According to experiments by v. Payr, communicated by Rochleder (Jahresb. 1857, p. 522), the crystals obtained by Müller were nothing but sulphate of potassium, which, however, does not agree with Müller's statement that they were soluble in alcohol and ether.

The seeds and flower-buds of *Tr. majus* pickled with vinegar are sometimes used instead of capers.

TROPINE. $C^8H^{15}NO$. (Kraut, Ann. Ch. Pharm. cxxviii. 280; cxxxiii. 87; Jahresb. 1863, p. 448; 1865, p. 448.)—An organic base, produced, together with atropic acid,* by the decomposition of atropine with alkalis:

$$\underset{\text{Atropine.}}{C^{17}H^{23}NO^3} = \underset{\text{Atropic acid.}}{C^9H^8O^2} + \underset{\text{Tropine.}}{C^8H^{15}NO.}$$

Atropine, heated with hot saturated baryta-water, disappears almost entirely, while only traces of a volatile base are produced. On precipitating the baryta from the resulting solution by carbonic acid, atropate of tropine remains in solution; and on agitating the filtered liquid with hydrochloric acid and ether, the atropic acid is dissolved by the ether, while hydrochlorate of tropine remains in the watery liquid. The base separated from this salt by silver-oxide solidifies in the crystalline form over oil of vitriol, and, when distilled at a temperature above 230°, passes over as a turpentine-like mass, and ultimately forms crystals containing $C^8H^{15}NO.\frac{1}{2}H^2O$.

---

* The name "atropic acid" has also been given to an imperfectly known acid, said by Richter to exist in belladonna (i. 474).

Atropine is likewise resolved into atropic acid and tropine, by the action of fuming hydrochloric acid.

Tropine is inodorous in the cold, but gives off odorous vapours when heated. It has a strong alkaline reaction, dissolves easily in water and in alcohol, and remains as an oil on evaporation. From solution in anhydrous ether, it crystallises over oil of vitriol in colourless anhydrous tables, $C^8H^{15}NO$, which melt at 61·2°. It does not absorb carbonic acid from the air, forms salts which crystallise well, and its aqueous solution precipitates the oxides of silver and copper, the precipitates not being soluble in excess of the reagent. From the solution of hydrochlorate of tropine, $C^8H^{15}NO.HCl$, strong potash-ley throws down oily drops, soluble in ether and in water.

The *chloroplatinate*, $2(C^8H^{15}NO.HCl).PtCl^4$, forms large orange-red crystals, easily soluble in water, but insoluble in alcohol. The double salts formed by the hydrochlorate with mercuric chloride, and by the hydriodate with mercuric iodide, are also sparingly soluble, and easily crystallisable. Auric chloride forms, in the solution of the hydrochlorate, a yellow precipitate, which melts and dissolves in warm water, and then crystallises.—*Picrate of tropine*, $C^8H^{15}NO.C^6H^3(NO^2)^3O$, is a yellow precipitate, which crystallises from water in needles.—*Atropate of tropine*, $C^8H^{15}NO^2.C^9H^8O^2.4H^2O$, is uncrystallisable, nearly solid, and ropy at ordinary temperatures, deliquescent at higher temperatures. In a 2 per cent. aqueous solution it does not produce dilatation of the pupil.

Tropine is not decomposed by boiling with hydriodic acid, or by heating to 140°, with hydrochloric acid. When distilled with dry hydrate of barium, it gives off ammonia and methylamine, together with other products.

Hydriodate of Ethyltropine, $C^8H^{14}(C^2H^5)NO.HI$, is easily formed by dissolving tropine in ethylic iodide. The free base separated from it by silver-oxide is a brown amorphous mass, which is insoluble in ether, soluble in absolute alcohol, and does not take up another atom of ethyl when treated with ethylic iodide.—The *platinum-salt*, $2[C^8H^{14}(C^2H^5)NO.HCl].PtCl^4$, is a light-yellow crystalline powder, precipitable by alcohol.

TRUFFLE. *Tuber cibarium* (*Lycopodon tuber*, L.).—An edible fungus, belonging to the family of the Gasteromycetes, forming round, blackish, warty knobs, yellowish-white within, veined like nutmegs, having a peculiar, agreeable, musklike odour, and aromatic taste. Truffles grow underground, often in groups: they occur in all temperate climates, especially in oak, beech, and chestnut-woods, and thrive best in a calcareous marly soil.

The aroma of the truffle is very volatile, and passes over with water in distillation. According to Lefort, truffles, when perfectly ripe, contain about 70 per cent. water. The organic constituents of the truffle are mannite, malic acid, citric acid, a non-saponifiable fat, besides the ordinary constituents of vegetable substances. Glucose, which (according to Vauquelin, Braconnot, and Lefort) occurs in *Agaricus edulis*, is not found in truffles (according to Lefort). The peculiar odoriferous principle of the truffle does not belong to the class of volatile oils: the colouring-matter exists chiefly in the spores.

TSCHEFFKINITE or **TSCHEWKINITE.** A silicotitanate of iron, cerium, &c., occurring massive and apparently amorphous, near Miask in the Ilmen Mountains. It is nearly opaque, with velvet-black colour, dark-brown streak, and strong vitreous lustre. Hardness = 5·0 to 5·5. Specific gravity = 4·50 to 4·55. Fracture flat conchoïdal. When heated before the blowpipe, it quickly glows, swells up very strongly, turns brown, and melts to a black bead. With fluxes it gives the reactions of iron, manganese, and silica. When heated in a tube, it leaves a little water. It dissolves in hydrochloric acid, leaving a jelly of silica. It contains, according to an approximate analysis by H. Rose (Pogg. Ann. lxii. 591):

SiO^2.	TiO^2.	CeO; LaO; DiO.	FeO.	CaO.	MgO.	MnO.	K^2O; Na O.
21·04	20·17	47·29	11·21	3·50	0·22	0·83	0·12;

whence its composition appears to be expressible by the formula $M''SiO^3.M''TiO^3$. A mineral from Coromandel, analysed by Damour (Jahresb. 1861, p. 824) appears to have the same composition. Another mineral, analysed by Schubin (Berz. Jahresb. xxvi. 373), and designated as tschewkinite, has been shown by Kokscharow to consist of orthite.

TSCHEN. Chinese coins of brass-yellow to bronze-yellow colour, containing (in 100 pts.) 55 to 64 per cent. copper, 26 to 35 zinc, generally from 1 to 2 per cent. tin. 2 to 4 per cent. iron, and between 1 and 6 per cent. lead; some of them contain also small quantities of antimony, arsenic, and nickel. (Pöpplein, Chem. Centr. 1859, p. 484.)

TSCHERMIGITE. Ammonia-alum (p. 580), occurring in a bed of lignite at Tschermig in Bohemia; also, according to Peters (Leonh. Jahresb. f. Min. 1861, p. 566), in that of Tokod, near Gran in Hungary.

TSCHEWKINITE. Syn. with TSCHEFFKINITE.

TSCHORNOSEM. Russian black earth. (See SOILS, p. 344.)

TSE-HONG. A mixture of white lead with alumina, ferric oxide, and silica, used by the Chinese as a red colour for painting on porcelain. (Salvétat.)

TSING-LIEN is another red colour, used for porcelain-painting, consisting chiefly of stannic and plumbic silicates, together with small quantities of oxide of copper, or cobalt and metallic gold. (Salvétat.)

TUBER CIBARIUM. Syn. with TRUFFLE.

TUESITE. A mineral allied to lithomarge or kaolin, occurring on the banks of the Tweed. It is massive, compact, with a bluish-white colour, and slightly waxy to dull lustre; opaque; sectile. Hardness = 2·5. Specific gravity = 2·4 to 2·6. Before the blowpipe it becomes light-blue and brittle, and forms a colourless glass with borax. The following analyses are by Thompson and Richardson (*Thomson's Outlines of Mineralogy*, i. 244):

SiO^2.	Al^2O^3.	CaO.	MgO.	FeO.	H^2O.		
44·30	40·40	0·75	0·50	. .	13·50	=	99·45.
43·80	40·10	0·64	0·55	0·94	14·21	=	100·24.

TUFA, CALCAREOUS. This name is applied to agaric mineral, or rock-milk (iii. 697), when so hard as not to be friable.

TUFA, VOLCANIC. Earthy or compact masses with white fracture, consisting of the hardened mud formed by mixture of volcanic ash (i. 420) with water.

TULIP-TREE. *Liriodendron tulipifera.*—The root-bark of this tree is said by Emmet to contain a crystallisable bitter principle called liriodendrin (iii. 726), which, however, Bouchardat was unable to prepare. The latter, however, obtained from tulip-tree bark a crystalline body, which he called piperin.

TULUCUNA, TULICOONA, or **TALLICOONA OIL.** Syn. with CARAPA-OIL (i. 749).

TULUCUNIN. $C^{20}H^{14}O^4$.—A crystallisable bitter principle, contained, according to Caventou (J. Pharm. [3], xxxv. 189; Jahresb. 1859, p. 583), in the bark of *Carapa Tulucuna.* Is is prepared by exhausting the aqueous extract of the bark with alcohol, mixing the solution with milk of lime, evaporating it after the insoluble matter has settled down, and treating the residue with chloroform. The resulting solution, when left to evaporate, yields tulucunin as a light-yellow, amorphous, resinous mass, having a very bitter taste, slightly soluble in water, easily soluble in alcohol and in chloroform, insoluble in ether. It is turned blue by sulphuric acid in the cold, and by oxalic, tartaric, or citric acid when heated.

TUNGSTATES. See p. 904.

TUNGSTEN: also called Wolfram. *Atomic weight*, 184. *Symbol*, W.—A metallic element, occurring as tungstate of iron and manganese in wolfram, a mineral somewhat abundant in Cornwall, Saxony, Bohemia, and other localities: it occurs also as tungstate of calcium (scheelite or tungsten) in Bohemia, Saxony, and other places; and as tungstate of lead (scheeletine) at Zinnwald in Bohemia, Bleiberg in Carinthia, and in Chile.

Metallic tungsten is obtained: 1. By heating trioxide of tungsten (tungstic oxide or anhydride) to bright redness in a stream of hydrogen.—2. By mixing the trioxide to a stiff paste with oil, charring the mixture, and then heating it intensely for several hours in a crucible lined with charcoal.—3. By passing the vapour of tungstic chloride or oxychloride mixed with hydrogen through a red-hot glass tube. (Wöhler, Ann. Ch. Pharm. xciv. 255.)

4. By passing the vapour of tungstic chloride over strongly heated sodium, and washing out the resulting sodium-chloride with water. (A. Riche, Ann. Ch. Phys. [3], l. 5.)

5. By igniting nitride of tungsten in hydrogen-gas, or in a porcelain crucible surrounded with charcoal-powder. (Wöhler, Jahresb. 1850, p. 303.)

Tungsten obtained by the first process is described by Wöhler as a steel-grey powder, which melts into globules at a very intense heat. According to Riche, the metal obtained as above forms small crystalline grains, which acquire metallic lustre by burnishing, and scratch glass with facility; it is infusible in the strongest forge-fire, but may be melted by the current of a Bunsen's battery of 200 pairs, being partially oxidised at the same time, and burning with a blue flame. The metal obtained by the second process is also heavy, of iron-grey colour, very hard, and difficult of fusion. The third process yields the metal as a shining, dark steel-grey, specular deposit, which may be detached from the glass in hard brittle crusts.

The specific gravity of tungsten reduced by hydrogen is 17·2 to 17·6 (**Wöhler**); 17·9 to 18·2 (Bernoulli, Jahresb. 1860, p. 152); that of the metal reduced by charcoal is 17·1 to 17·2 (Bernoulli); of that reduced from the chloride by hydrogen, 16·54. (Wöhler.)

Tungsten reduced from the nitride (4) is pulverulent, and has a specific gravity of 17·5; that obtained by igniting acid potassium-tungstate in hydrogen, has a specific gravity of 18·26. (Wöhler.)

Pulverulent tungsten heated in the air, burns easily to tungstic oxide; but compact tungsten may be heated in the air without sensible change, excepting at the very high temperature of the electric current, as above mentioned. Nitric acid and nitromuriatic acid convert tungsten into tungstic acid, and the same change is produced by heating it in contact with the alkalis or with nitre. Pulverulent tungsten is also oxidised and dissolved, by boiling it in a solution of caustic alkalis or alkaline carbonates.

Tungsten forms two classes of compounds, in one of which it is tetratomic, and in the other hexatomic:

Tungstous Chloride, WCl^4.	Tungstic Chloride. WCl^6.
Tungstous Oxide, WO^2.	Tungstic Oxide, WO^3.

There are also compounds of intermediate composition, which may be regarded as resulting from the union of tungstous and tungstic compounds: *e.g.*, $W^2Cl^{10} = WCl^4.WCl^6$.

TUNGSTEN, ALLOYS OF. These alloys have not been much studied. Wöhler and Michel (Ann. Ch. Pharm. cxv. 102), by fusing 15 pts. tungsten-trioxide, 30 pts. cryolite, 30 pts. of a mixture of potassium- and sodium-chloride in equivalent proportions, and 15 pts. aluminium at a full red heat, obtained a regulus, which, when the excess of aluminium was dissolved out by dilute hydrochloric acid, left an alloy of tungsten and aluminium, Al^4W, as an iron-grey crystalline powder, of specific gravity 5·58, and appearing under the microscope to consist of rhombic prisms. This alloy is not attacked by concentrated acids in the cold, but is oxidised by hot nitric acid, with separation of yellow tungstic acid. Hydrochloric acid dissolves it with deep brown colour. It is decomposed by hot soda-ley, which dissolves the aluminium, and leaves pure tungsten.

Tungsten alloyed with steel in the proportion of 9 or 10 pts. of the former to 90° of the latter, yields an alloy of extraordinary hardness. According to F. A. Bernoulli, (Pogg. Ann. cxi. 573; Jahresb. 1860, p. 153), a very hard tungstiferous *cast-steel* may be obtained by fusing turnings of grey cast-iron with tungsten-trioxide. The reduction of this oxide to metallic tungsten is effected only by the mechanically mixed carbon of the grey cast-iron, not by that which is chemically combined with the iron; accordingly, white cast-iron fused with tungsten-trioxide does not yield tungsten-steel, and after addition of charcoal merely an alloy of tungsten and iron.

Copper, lead, zinc, antimony, bismuth, cobalt, and nickel unite with tungsten, only when the two metals are simultaneously reduced from their oxides. The alloys which they form are so difficultly fusible, that those which contain more than 10 per cent. tungsten do not yield reguline masses; and those which contain volatile metals decompose when strongly heated, leaving nothing but metallic tungsten. Iron is the only metal which alloys with tungsten in all proportions up to 80 per cent. of the latter, with which proportion a mass is formed, not fusible at any attainable temperature. (Bernoulli.)

TUNGSTEN, BROMIDES OF. (Bonnet, J. pr. Chem. x. 206.—Borck, *ibid.* liv. 254; Jahresb. 1851, p. 344.—Riche, Ann. Ch. Phys. l. 5; Jahresb. 1857, p. 185.—Blomstrand, J. pr. Chem. lxxxii. 408; Jahresb. 1861, p. 227.)—Tungsten heated in bromine-vapour unites directly with it, forming products, the composition of which has been variously stated by different chemists. According to Borck, the product consists partly of the tetrabromide, or tungstous bromide, WBr^4; partly of the pentabromide, or tungstoso-tungstic bromide, $W^2Br^{10} = WBr^4.WBr^6$, both of which sublime in black needles, the former, however, being more volatile than the latter, and very deliquescent.—According to Riche, tungsten heated to redness in bromine-vapour, is converted into the hexbromide or tungstic bromide, WBr^6, partly in the form of a fused mass, partly in sublimed needles, of a chestnut-brown colour. This compound, when exposed to moist air, is converted superficially into the violet oxybromide, WBr^4O, and finally into tungstic acid; water converts it immediately into tungstic acid, with brisk effervescence.—According to Blomstrand, the product of the action of bromine-vapour on heated tungsten consists mainly of the pentabromide, W^2Br^{10} (probably resulting from the combination of WBr^4 and WBr^6), mixed, if air and moisture have not been excluded, with the oxybromides, WBr^4O and WBr^2O^2. The black needles, described by Borck as the tetrabromide, consist, according to Blomstrand, of the former of these oxybromides.

The pentabromide, or tungstoso-tungstic bromide, W^2Br^{10}, after repeated tion, has a bluish-black colour; it boils and sublimes near its melting-point, giving off a dark purple-red vapour, which, on cooling, condenses to a compact crystalline mass, or to shining quadratic prisms. In contact with water or moist-air, it is converted into hydrobromic acid and blue oxide of tungsten, W^2O^5. Alkalis dissolve it, without evolution of hydrogen. When heated in contact with the air, it is converted into the oxybromide, WBr^2O^2, which sublimes. (Borck.)

Oxybromides.—Two of these compounds are known, derived from tungstic oxide, WO^3, by replacement of 1 and 2 at. oxygen by equivalent quantities of bromine.—*Tungstic dioxybromide*, WBr^2O^2 or $WBr^6.2WO^3$, first observed by Bonnet, is formed, together with the pentabromide, in the first stage of the reaction of bromine on metallic tungsten when air is not completely excluded; and in a purer state by the action of bromine on the dioxide. It forms yellow crystalline scales, of the colour of brass or mosaic gold. It is infusible, is resolved by heat into tungstic oxide and tungstic monoxybromide, and converted by water into tungstic acid. (Blomstrand.)

The *monoxybromide*, $WBr^4O = 2WBr^6.WO^3$ (described by Borck as the tetrabromide, p. 898), is best obtained by the action of bromine, at a gentle heat, on sulphide of tungsten (prepared in the wet way), or upon a mixture of tungstic oxide and charcoal; it likewise invariably occurs, as an intermediate product, when the pentabromide and the dioxybromide are simultaneously produced. Its colour is very much like that of the pentabromide, only of a lighter black-brown; its vapour is brown-red; it crystallises in woolly needles, and yields tungstic acid with water. (Blomstrand.)

The compound $W^2Br^{10}.W^2O^5$, described by Bonnet, does not appear to exist.

TUNGSTEN, CHLORIDES OF. (Wöhler, Pogg. Ann. ii. 345.—Malaguti, Berz. Jahresb. xv. 103.—H. Rose, *ibid.* xviii. 200.—Borck, J. pr. Chem. liv. 254; Jahresb. 1851, p. 345.—Riche, Ann. Ch. Phys. [3], l. 5; Jahresb. 1856, p. 372; 1857, p. 184.—Blomstrand, J. pr. Chem. lxxxii. 408; Jahresb. 1861, p. 228.—Forcher, Wien. Akad. Ber. xliv. 159; Jahresb. 1861, p. 232.—Debray, Compt. rend. lx. 820; Jahresb. 1865, p. 212.)—Chlorine, like bromine, acts directly upon tungsten, forming products, the composition of which has been variously stated by different chemists. According to recent investigations, however, the compounds obtained by heating metallic tungsten in dry chlorine-gas, are WCl^6 and W^2Cl^{10}, analogous to the bromides; but the hexchloride is more easily obtained in the separate state than the hexbromide, apparently because a lower temperature is sufficient for its formation. If oxygen is present, oxychlorides are also formed, analogous to the oxybromides above described. According to Wöhler and Borck, the tetrachloride, WCl^4, is obtained, as a dark-red compound, by heating tungsten in chlorine-gas; but, according to Blomstrand, this red product is obtained only when oxygen is present, and is really an oxychloride; the tetrachloride, indeed, does not appear to exist, at least in the separate state, not being formed even when one of the higher chlorides is heated in hydrogen-gas (Blomstrand). Riche, on the other hand, states that it is produced in this manner, but is very difficult to obtain pure, being easily resolved into the hexchloride and metallic tungsten.

Hexchloride of Tungsten, or *Tungstic Chloride*, WCl^6.—This compound is formed, together with the following, when tungsten burns in chlorine-gas; in smaller quantity also by heating sulphide of tungsten in chlorine; and, together with oxychlorides, by the action of chlorine on an ignited mixture of tungstic oxide and charcoal. It is less volatile than the pentachloride and oxychlorides, which may therefore be removed from it by sublimation. It forms dark-violet scales, or fused crusts, having a blackish-grey colour and bluish metallic iridescence; by careful sublimation it may be obtained in blackish-violet needles having a metallic aspect. It melts at 183° (Cahours), at 180° (Forcher), to a black liquid, and yields a dark-red vapour (Forcher); reddish-yellow (Blomstrand); it decrepitates on cooling (Blomstrand). The vapour-density, taken at the heat of boiling mercury, is, according to Debray, 11·50; at the heat of boiling sulphur, 11·86; the calculated density for a two-volume condensation is 13·75, which is considerably higher than the experimental numbers. Debray observes, however, that it is very difficult to obtain the hexchloride quite free from pentachloride (which has a lower vapour-density) even by repeated sublimation in chlorine-gas.* The hexchloride, heated in contact with the air, is converted into cinnabar-red flocks of WCl^4O, and soft yellowish-white flocks of hydrated tungstic acid, $WH^2O^4.H^2O$, or $WO^3.2H^2O$; in moist air, or in contact with water, it is completely resolved into hydrochloric and tungstic acids. It dissolves in alkalis, forming tungstates; with alcohol it yields ethylic chloride and blue tungsten-oxide, W^2O^5, which, in contact with the air, is quickly converted into yellow tungstic oxide. (Forcher.)

---

* J. Persoz (Ann. Ch. Phys. [4], i. 93; Jahresb. 1863, p. 213) regards tungsten as a metal belonging to the arsenic and antimony group, its oxides being represented by the formulæ Tu^2O^3, Tu^2O^4, Tu^2O^5, the chlorides and bromides by corresponding formulæ, and the atomic weight of the metal being 153·3. According to this view, the vapour-density of tungstic chloride, $TuCl^5$, should be $\frac{153 \cdot 3 + 5 \,.\, 35 \cdot 5}{2} \times 0 \cdot 0693 = 11 \cdot 46$, which agrees very nearly with Deville's determination.

The *Pentachloride*, or *Tungstoso-tungstic Chloride*, $W^2Cl^{10} = WCl^4.WCl^6$, is produced by the combustion of metallic tungsten in chlorine, and in smaller quantity by heating the sulphide in chlorine, mixed in both cases with the hexchloride, from which, and from the oxychloride formed at the same time, if moisture is present, it may be separated by sublimation, as its boiling-point lies midway between that of the hexchloride and that of the oxychloride (Forcher). The pentachloride is likewise obtained by gently heating nitride of tungsten in chlorine-gas, and by the action of chlorine on an ignited mixture of tungetic oxide and charcoal.

Pentachloride of tungsten forms dark-red needles, or larger crystals of a purple-red colour. It is more volatile than the hexchloride, melts to dark-red drops, and its vapour, which resembles nitrous anhydride, quickly condenses in soft crystalline masses. By water or moist air it is converted into yellowish-green tungstic acid; alkalis dissolve it slowly, with evolution of hydrogen, and transient-blue coloration, forming solutions of tungstates. (Forcher.)

According to Blomstrand, on the other hand, the pentachloride is much less volatile than the hexchloride, and to obtain it pure, the mixture of pentachloride and hexchloride, produced as above, must be heated in an atmosphere of hydrogen; care being taken that the heat does not rise too high, in which case metallic tungsten would be separated. The pentachloride thus obtained may be resublimed in hydrogen-gas, or better in carbonic anhydride. Its colour is like that of the hexchloride, but of a darker blackish-grey, without the violet tint. It melts and volatilises much less easily than the hexchloride; yields a greenish-yellow gas; crystallises readily in shining blackish needles; and solidifies from fusion in the crystalline form. Water decomposes it, with considerable rise of temperature, and separation of a blue-black oxide, while the liquid assumes a deep greenish-yellow colour, which it loses after some time, and more quickly when heated, depositing a greenish precipitate. The same appearances, but with deeper colours, are produced by treating the compound with alkalis or with hydrochloric acid.

It is clear, from the preceding statements, that the so-called pentachlorides obtained by Blomstrand and by Forcher were not identical. It is most probable that Forcher's compound is the true pentachloride, inasmuch as Riche (Jahresb. 1856, p. 373), by heating the hexchloride in hydrogen-gas, obtained, not the pentachloride, but the tetrachloride, WCl^4, though he states that this compound is very difficult to prepare in a definite state, being easily resolved, by too strong a heat, into metallic tungsten and the hexchloride. Altogether the chemistry of the chlorides and bromides of tungsten is still in a very unsatisfactory state, and requires further investigation.

Oxychlorides.—Two of these compounds are known, analogous to the oxybromides, and producible by similar reactions.—*Tungstic dioxychloride*, WCl^2O^2, or $WCl^6.2WO^3$, is most easily prepared by heating the dioxide in chlorine-gas; it is also produced, in considerable quantity, when a mixture of the trioxide and charcoal is ignited in chlorine-gas, especially when the proportion of charcoal to tungstic oxide is as 5 : 1 or 4 : 1. Blue oxide of tungsten also yields this compound when heated in chlorine, either alone or with charcoal; and it is even produced, though in small quantity and impure, when dry chlorine is passed over native wolfram, finely pulverised and ignited (Forcher). The dioxychloride forms lemon-yellow or deep golden-yellow flocks, or shining scales, which volatilise between 265° and 267°, in vapours of a deep but pure yellow colour (colourless, according to Blomstrand). It is converted, slowly by moist air, more quickly by water, into hydrochloric acid and yellow hydrated tungstic acid, $WH^2O^4.H^2O$. Alkalis dissolve it, forming tungstates. (Forcher.)

The *monoxychloride*, WCl^4O, or $2WCl^6.WO^3$, is formed when the preceding compound is heated, the condition essential to its formation being not so much a high temperature, as a sudden raising of the heat above 140°. It is also invariably produced, together with the yellow dioxychloride, in the processes above given for the preparation of the latter, and when tungsten or the sulphide is burnt in chlorine-gas, the presence of air or moisture not being completely excluded. It is of a cinnabar or scarlet colour, but sometimes crystallises in slender needles of a lighter red tint, or in orange-yellow flocks made up of slender crystals; in fused crusts it has a carmine colour. It is the most fusible and volatile of all the chlorine-compounds of tungsten, and forms a deep reddish-yellow vapour, which, in contact with the air, is converted into yellowish-white hydrated tungstic acid. By water and moist air, it is quickly converted into hydrochloric and tungstic acids, and by alkalis into a tungstate. (Blomstrand; Forcher.)

The vapour-density of this oxychloride was found by Debray to be 10·74 at the temperature of boiling mercury, 10·27 at that of boiling sulphur. The density, calculated from the formula WCl^4O, for a two-volume condensation, is 11·86; according to the formula and atomic weight proposed by Persoz (footnote, p. 899), it is 9·87.

TUNGSTEN, DETECTION AND ESTIMATION OF. 1. *Blowpipe Reactions.*—All tungsten-compounds form colourless beads with borax and phosphorus-salt, in the outer blowpipe-flame. With borax, in the inner flame, they form a yellow glass, if the quantity of tungsten is somewhat considerable, but colourless with a smaller quantity. With phosphorus-salt in the inner flame they form a glass of a pure blue colour, unless metallic oxides are present, which modify it; in presence of iron, the glass is blood-red, but the addition of metallic tin renders it blue.

2. *Reactions in Solution.*—The only soluble compounds of tungsten are the tungstates of the alkali-metals and alkaline earth-metals, most of the metatungstates (formed from ordinary tungstates by addition of tungstic acid or abstraction of part of the base), and certain sulphotungstates. Insoluble tungsten-compounds may be decomposed by fusion with alkaline carbonate and nitrate, whereby an alkaline tungstate is formed, which may be dissolved out by water. The behaviour of tungsten-solutions towards many reagents, differs according as the solution contains ordinary tungstic acid or metatungstic acid, the metatungstates being more soluble than the corresponding tungstates; but the following characters are common to both modifications:—

1. A soluble tungstate, supersaturated with sulphuric, hydrochloric, phosphoric, oxalic, or acetic acid, yields, on the introduction of a piece of *zinc*, a beautiful blue colour, arising from the formation of blue oxide of tungsten; this effect is not produced with nitric, tartaric, or citric acid.—A soluble tungstate, mixed with *sulphide of ammonium*, and then with excess of acid, yields a light-brown precipitate of tungstic sulphide, soluble in sulphide of ammonium.—*Sulphydric acid* does not precipitate the acidulated solution of a tungstate, but turns it blue, owing to the formation of the blue oxide. These characters, together with the blowpipe-reactions, are sufficient to distinguish tungsten from all other metals. The distinguishing characters of tungstates and metatungstates will be described further on (pp. 905, 912).

3. *Estimation and Separation.*—Tungsten is always estimated in the form of tungstic oxide, WO^3. When tungstic acid is present in a solution not containing any other fixed substance, it is sufficient to evaporate to dryness, and ignite the residue. The tungstic oxide is then obtained in a state of purity, and contains 79·3 per cent. of the metal. Tungstous oxide, WO^2, is easily converted into tungstic oxide by fusion with carbonate of sodium.

The best method of separating tungstic acid from the fixed alkalis is to treat the solution, after exact neutralisation with nitric acid, with a solution of *mercurous nitrate*. Mercurous tungstate is then precipitated, and the mercury may be expelled from the dry precipitate by careful ignition in a good draught.

The separation of tungstic acid from the earths may be effected by decomposing the compound with *nitric acid*, and treating the decomposed mass with *carbonate of ammonia*, which dissolves the tungstic acid.

Tungstic acid may be readily separated from many metallic oxides—such as the oxides of iron, manganese, nickel, cobalt, lead, &c.—by fusing the whole with *carbonate of sodium*, and digesting the fused mass with water, which dissolves the tungstic acid, and leaves the oxides undissolved.

From titanic, tantalic, and niobic acids, tungstic acid is separated by *ammonia*, which dissolves only the latter. The separation is facilitated by addition of *ammonium-sulphide*. If, however, the substance containing these acids has been ignited, mere digestion in ammonia, or sulphide of ammonium, will not dissolve the tungsten: in this case it is best to fuse the mixture with sulphur and carbonate of sodium, whereby the tungsten will be converted into soluble sulphotungstate of sodium.

The separation of tungstic from chromic acid may be effected by treating the solution with excess of *hydrochloric acid*, and boiling with *alcohol*. The chromic acid is thereby reduced to chromic oxide, which may be precipitated by ammonia, the tungstic acid remaining in solution.

To separate tungstic from molybdic acid, it is best to dissolve the two in an alkali, add tartaric acid and excess of hydrochloric acid, which produces no precipitate, and throw down the molybdenum as sulphide by *sulphydric acid*.

From silicic acid, tungstic acid may be separated by fusing the mixture with *acid sulphate of potassium*, and digesting the fused mass with water, which will dissolve the tungsten as alkaline tungstate, and leave the silica. The tungstic acid may then be precipitated from the solution by mercurous nitrate. Tungsten has not, however, been found in any natural silicate.

The separation of tungsten from tin is especially important, as wolfram is often associated with tin-ores, and the two metals likewise occur together in many tantalites and columbites. When stannic and tungstic acid exist together in solution, they are easily separated by sulphydric acid, which precipitates the tin from the acidulated liquid as stannic sulphide, and leaves the tungsten in solution. When stannic and tungstic oxides are mixed together in the solid state, the separation may be effected by igniting a weighed quantity of the mixture in a covered porcelain crucible, and passing a stream of hydrogen-gas into the crucible, through a hole in the cover. The loss of weight thereby occasioned is about equal to that which would correspond to the complete reduction of the tin-oxide to metal, and of the trioxide of tungsten to dioxide. The ignited residue is then boiled with hydrochloric acid, the tin is precipitated from the filtered solution by hydrochloric acid, and the precipitated sulphide is converted by roasting into stannic oxide. Lastly, the dioxide of tungsten is converted, by ignition in the air, into trioxide, and the latter is weighed. The separation cannot be effected by fusing the mixture with acid sulphate of potassium (H. Rose and Dexter, Pogg. Ann. xcii. 335; Jahresb. 1854, p. 731). According to Rammelsberg (Pogg. Ann. cxx. 66; Jahresb. 1863, p. 678), the separation effected by the preceding method is not complete, unless the heat applied is strong enough to reduce the tungsten as well as the tin to the metallic state, and in that case a small quantity of tin is volatilised. He recommends, as a better method, to ignite the mixture of the two oxides repeatedly, and till no more loss of weight takes place, with 6 or 8 pts. of sal-ammoniac. To prevent the deposition of stannic oxide on the outside of the crucible, it should be enclosed within a larger one, and heated rather quickly. The residual tungstic oxide is finally ignited in contact with the air.

4. *Atomic Weight of Tungsten.*—The older determinations of the atomic weight of this metal, by Berzelius and others, did not lead to correct results. Schneider (Ann. Ch. Pharm. lxxvii. 261), by reducing tungstic oxide, WO^3, in a current of hydrogen, found that 100 pts. of the oxide yielded 79·316 pts. of metallic tungsten; and on reoxidising the metal, he found that 79·327 pts. of tungsten yielded 100 pts. of the trioxide. The mean of these results gives W = 184·12. Marchand (*ibid.* lxxvii. 261), by similar experiments of reduction and oxidation, found, as a mean value, W = 184·1; Borck (J. pr. Chem. liv. 254) found, in like manner, the number 184; and the same result has been obtained by Dumas (Ann. Ch. Pharm. cxiii. 23). This last number may be regarded as the true atomic weight of tungsten, supposing, as most of the chemical relations of tungsten seem to show, that its highest oxide has the composition WO^3, and the corresponding chloride WCl^6.

The proposal of Persoz to regard tungstic oxide as Tu^2O^3, the corresponding chloride as $TuCl^3$, the atomic weight of tungsten being 153·3, has already been noticed (p. 899). The agreement of the vapour-density of tungstic chloride calculated from this formula with Debray's experimental number, is certainly remarkable; but, on the other hand, the specific heat of the metal, as determined by Regnault, agrees better with the atomic weight 184 (according to the law of Dulong and Petit) than with 153·3 (see HEAT, iii. 30); moreover the composition of the tungsten-compounds is, on the whole, more conveniently represented by the ordinary formula, than by those suggested by Persoz.

TUNGSTEN, FLUORIDE OF. Tungstic oxide, after ignition, is but sparingly dissolved by hydrofluoric acid; precipitated tungstic acid forms, with hydrofluoric acid, a yellow milky liquid, soluble in a large quantity of water. The solution, when slowly evaporated, yields a yellow syrup, which at a higher temperature gives off a portion of its acid, and solidifies to a greenish fissured mass. This mass is not decomposed by ignition in a close vessel; it redissolves imperfectly in water, forming a milky liquid; the insoluble part consists of tungstic acid, which retains a portion of the hydrofluoric acid so obstinately, that the latter can only be expelled by igniting the tungstic acid with lumps of ammonium-carbonate. The solution contains tungstic acid, with excess of hydrofluoric acid. (Berzelius.)

Tungstic fluoride, WF^6, forms, with the more basic metallic fluorides, compounds which have not yet been isolated, and are known only in combination with tungstates (Berzelius). These double oxyfluorides, which are produced by treating tungstates with hydrofluoric acid, appear to be isomorphous with the corresponding fluosilicates, fluostannates, and fluotitanates. Thus cupric oxyfluotungstate, $CuWO^2F^4$, and cupric fluotitanate, $CuTiF^6$, form isomorphous compounds with fluoride of ammonium; whence it appears as if oxygen could, in certain cases, replace fluorine atom for atom, although the ratio of the atomic weights of these elements is not the same as that of their equivalents. (Marignac, Ann. Ch. Pharm. cxxv. 362; Jahresb. 1862, p. 144.)

TUNGSTEN MINERAL. Native tungstate of calcium, also called scheelite (p. 907).

TUNGSTEN, NITRIDE OF. When either of the chlorides of tungsten is placed at the sealed end of a long glass tube, and in front of it a few dried lumps of sal-ammoniac, the empty part of the tube then heated to redness, and the heat gradually extended to the closed end, so that the two salts may be volatilised and mix in the gaseous form at a red heat, double decomposition takes place; and after the excess of sal-ammoniac has been removed, the entire inner surface of the tube is found to be covered with a black specular semimetallic coating, which may be separated, partly in brittle crusts, partly as a black powder. This product consists either of nitride of tungsten, or of a compound of that substance with an amide of tungsten, called by Wöhler tungsten-nitretamide, and containing either $2WN^2.W(NH^2)^2$, or $W^2N^2.2W(NH^2)^2$. It gives off a large quantity of ammonia when fused with potash, and is converted into tungstic oxide by ignition in the air. By the action of ammonia-gas on tungstic oxide, at a moderate red heat, compounds are formed containing nitride, amide, and oxide of tungsten. When finely-divided tungstic oxide, spread in a thin layer on the inside of a glass tube, is heated in dry ammonia-gas, tungsten-nitretamidoxide, $3WN^2.2W(NH^4).2WO^3$, is formed, as a black substance which is not decomposed by acids or alkalis, gives off ammonia when heated alone, and when heated in the air, burns with vivid glow to yellow tungstic oxide. (Wöhler, Ann. Ch. Pharm. lxxiii. 190; cv. 258; Jahresb. 1850, p. 303; 1858, p. 158.)

TUNGSTEN, OXIDES OF. Tungsten forms three oxides—viz. WO^2, WO^3, and W^2O^5—neither of which exhibits basic properties, so that there are no salts of tungsten in which the metal replaces the hydrogen of an acid, or takes the electropositive part. The dioxide forms a definite compound with soda, and the trioxide exhibits decided acid tendencies, uniting with basic metallic oxides, and forming definite crystallisable salts called tungstates. The oxide, W^2O^5, may be regarded as a compound of the other two, that is as a tungstate of tungsten, $WO^2.WO^3$.

Dioxide of Tungsten, or **Tungstous Oxide,** WO^2.—This oxide is obtained as a brown powder when tungstic oxide is reduced by hydrogen at a temperature not exceeding low redness. Tungstic oxide may also be deprived of oxygen in the wet way, by pouring diluted hydrochloric acid over it, and placing zinc in the liquor: the trioxide then gradually changes into the dioxide, in the form of brilliant crystalline plates of a copper-red colour. No saline compounds of this oxide with acids are known. When digested in a strong solution of potassic hydrate, it dissolves, with disengagement of hydrogen-gas and formation of potassic tungstate.

A *tungstite of sodium*, $Na^2W^2O^5 = Na^2O.2WO^2$, is obtained by adding to fused tungstate of sodium as much tungstic oxide as it will take up, and exposing the mass, at a red heat, to hydrogen-gas. After dissolving out the neutral undecomposed tungstate by water, the tungstite remains in golden-yellow scales and regular cubes, possessing the metallic lustre and a striking resemblance to gold. This compound is not decomposed by sulphuric, nitric, or nitromuriatic acid, or by alkaline solutions, but yields to hydrofluoric acid. It cannot be prepared by uniting soda directly with the dioxide.

Trioxide of Tungsten, Tungstic Oxide or **Anhydride,** WO^3.—This oxide occurs native as tungstic ochre, wolfram-ochre, or wolframine, accompanying wolfram or other ores of tungsten, in Cumberland, at St. Leonard near Limoges, in Mourne County, Connecticut, and in Cabarras County, North Carolina; sometimes in cubes, sometimes pulverulent and earthy, of a bright-yellow or yellowish-green colour.

Tungstic oxide is prepared from scheelite (native tungstate of calcium), or from wolfram:

1. Finely-pulverised scheelite is decomposed by nitric or hydrochloric acid; the soluble nitrate or chloride of calcium is washed out with water, and the remaining tungstic acid is ignited.

2. Finely-pulverised wolfram is repeatedly digested with strong hydrochloric acid, at last with addition of a little nitric acid, to dissolve out the iron and manganese, the tungstic acid which remains is washed and dissolved in aqueous ammonia; the solution evaporated to dryness; and the residual acid ammonium-salt heated in contact with the air: tungstic oxide then remains in pale-yellow scales.—3. One pt. of pulverised wolfram is fused with 2 pts. carbonate of potassium; the fused mass is digested with water; the filtered solution mixed with sal-ammoniac and evaporated; and the residue is ignited in a crucible, and then treated with zinc and hydrochloric acid, whereby brown dioxide of tungsten is produced, which, when ignited in the air, yields the pure trioxide (Wöhler).—4. Pulverised wolfram is fused for an hour with 2 pts. chloride of calcium; the fused mass is treated with water, which leaves tungstate of calcium undissolved; this salt is decomposed by boiling with hydrochloric acid; the residual tungstic acid is dissolved in ammonia (to free it from silica); and the ammonium-salt, obtained on evaporating the filtrate, is ignited in contact with the air. (Wöhler.)

The solution of alkaline tungstate obtained by either of the preceding methods may also be mixed with mercurous nitrate, whereby a precipitate of mercurous tungstate is obtained, which on ignition leaves pure tungstic oxide.

Anhydrous tungstic oxide is a lemon-yellow or sulphur-yellow powder, darker or lighter according to the mode of preparation. Nordenskjöld, by fusing the tungstic hydrate with borax in a pottery-furnace, obtained the anhydrous oxide in small transparent tables or short prisms belonging to the trimetric system. Debray (Compt. rend. lv. 287), by strongly igniting a mixture of sodic carbonate and tungstate in a current of hydrochloric acid gas, obtained the tungstic oxide in octahedral crystals—some small and translucent with yellowish colour, others larger, black, and opaque.

Tungstic oxide has a specific gravity of 5·27 (Herapath), 6·12 (d'Elhujar), 7·14 (Krosten). It is tasteless, insoluble in water and in most acids, only slightly soluble in strong hydrochloric and in hydrofluoric acids. When heated, it becomes transiently darker and greenish, at very high temperatures, but, according to Bernoulli (Jahresb. 1860, p. 153), the greenish and the yellow oxides have exactly the same composition. Tungstic oxide melts at the heat of a forge-fire, and volatilises quickly when heated on charcoal before the oxyhydrogen-blowpipe. When heated for ten or twenty minutes before the oxyhydrogen-blowpipe, in a covered platinum-crucible, it forms a crystalline crust, the surface of which exhibits crystals apparently formed by sublimation; no sublimate is, however, formed on the sides of the crucible. In hydrochloric acid gas, tungstic oxide volatilises easily, forming a sublimate of pale-yellow stellate needles. (Schafarik.)

Tungstic oxide turns greenish on exposure to light, probably in consequence of the reducing action of organic particles in the air. According to Liesegang (Jahresb. 1865, p. 214), when exposed to light in contact with *organic substances*, it is reduced to blue oxide. When heated to redness, in contact with *charcoal* or *hydrogen*, it is reduced to dioxide or metal, according to the temperature and the duration of the action; by ignition with *potassium* or *sodium*, it is reduced to metal; by ignition in dry *ammonia-gas*, it is converted into oxynitretamide of tungsten (p. 903), by heating with sulphur to blue oxide.—When it is heated with *pentachloride of phosphorus*, oxychloride of phosphorus passes over, together with small quantities of tungstic chloride and oxychloride, WCl^4O; the greater part of the tungsten, however, remains in the residue which, when treated with water, yields hydrochloric acid and a mixture of tungstic oxide with the blue oxide. (Gerhardt and Chiozza, Ann. Ch. Pharm. lxxxvii. 290; Jahresb. 1853, p. 395; see also Schiff, *ibid.* 1857, p. 106; Weber, *ibid.* 1859, p. 79.)

Tungstic oxide is also reduced by *zinc* and *hydrochloric acid*, by *stannous chloride*, or by boiling with *organic bodies* and water—first to the blue oxide, then, by further reduction, to the brown dioxide.

TUNGSTIC ACID.—Tungstic oxide dissolves in aqueous alkalis or alkaline carbonates, slowly in the cold, more quickly at the boiling heat, forming solutions of tungstates; and, on precipitating the hot solutions of these salts with an acid, tungstic monohydrate, or tungstic acid, $H^2WO^4 = H^2O.WO^3$, is obtained as a yellow precipitate; it dissolves in hydrofluoric acid, and separates from the solution in crystals on evaporation.

By mixing a dilute solution of an alkaline tungstate with hydrochloric, nitric, or sulphuric acid, a white gelatinous precipitate is obtained, having, when air-dried, the composition of tungstic dihydrate or hydrated tungstic acid, $2H^2O.WO^3 = H^2WO^4.H^2O$.—This hydrate is likewise formed by the decomposition of tungstic chloride, or oxychloride, with water; after washing and drying, it is sometimes yellowish-grey and translucent, sometimes black and opaque; when finely pulverised, it is said to dissolve in 200 pts. of boiling, and 300 pts. of cold water. (Anthon, J. pr. Chem. ix. 6.—Riche, Ann. Ch. Phys. [3], l. 5.)

Tungstic acid reddens litmus, and dissolves in aqueous fixed alkalis, and in ammonia.

TUNGSTATES.—Tungstic acid unites with bases in various and often in very unusual proportions. The salts have been examined by Berzelius (Pogg. Ann. iv. 147; viii. 267), Anthon (J. pr. Chem. viii. 399; ix. 6, 8, and 337), Margueritte (J. Pharm. [3], vii. 222), Laurent (Ann. Ch. Phys. [5], xxi. 54), Lotz (Ann. Ch. Pharm. xci. 49; Jahresb. 1854, p. 339), Scheibler (Berl. Akad. Ber. 1860, p. 208; Jahresb. 1860, p. 154), and Marignac (Ann. Ch. Phys. [3], lxix. 5; Jahresb. 1862, p. 143); but the results of these investigations are not very accordant, inasmuch as the salts often differ considerably in composition and properties, according to the mode of preparation adopted. Laurent, from the behaviour of the ammonium-tungstates, was led to admit the existence of five isomeric or polymeric modifications of the tungstates; but from recent investigations, it appears that the number of modifications of tungstic acid and its salts may be reduced to two, viz.:

1. Ordinary tungstic acid, which is insoluble in water, and forms insoluble salts with all metals, except the alkali-metals.

2. Metatungstic acid, which is soluble in water, and forms soluble salts with nearly all metals.

Ordinary Tungstates.

Ordinary tungstic acid forms both neutral and acid salts. The neutral tungstates contain M^2WO^4, or $M^2O.WO^3$; the acid salts were formerly supposed to be either diacid, $M^2O.2WO^3 = M^2WO^4.WO^3$, or triacid, $M^2O.3WO^3 = M^2WO^4.2WO^3$. According to Scheibler, however, the acid tungstates have in general the formula $3M^2O.7WO^3$ $4H^2O$, and may be regarded as double salts composed of sesquitungstates and tetratungstates—*i.e.*, as $2M^2O.3WO^3 + M^2O.4WO^3$, or perhaps of diacid and triacid salts, $2(M^2O.2WO^3) + M^2O.3WO^3$ (according to Persoz, $2M^2O.2H^2O.3Tu^2O^5$). According to Laurent, the empirical formula of the acid salts is $5M^2O.12WO^3.xH^2O$; and according to Marignac, this formula agrees with the analytical results more nearly than that given by Scheibler; but the percentage composition deduced from the one formula differs so little from that given by the other, that it is difficult to decide between the two by analysis. Scheibler's formula, however, which is the more simple of the two, is generally preferred. Marignac designates these salts, which he regards as containing 5 at. basic oxide to 12 at. tungstic anhydride, or 5 at. monatomic metal to 6 at. tungsten, as paratungstates; he finds that the ammonium-salt having this composition cannot be converted into the neutral tungstate by digestion with ammonia. They are produced more easily, and crystallise better, than acid tungstates containing any other proportion of base and acid.

Of the ordinary tungstates, only those of the alkali-metals and magnesium are soluble in water, and these are but sparingly soluble. They may be prepared in the wet way by dissolving tungstic oxide or tungstic acid in alkalis, or alkaline carbonates, most easily at the boiling heat. They are also easily formed by fusing tungstic oxide with the hydrates, carbonates, or acid sulphates of the alkali-metals. They have a bitter metallic taste, and excite an unpleasant feeling in the throat. The insoluble tungstates are prepared by igniting tungstic oxide with metallic oxides or carbonates, or from the soluble salts by precipitation; also by fusing an alkaline tungstate with the corresponding metallic chlorides (chloride of calcium, for example); on exhausting the mass with water, the insoluble tungstate remains in the crystalline state (Manross, Ann. Ch. Pharm. lxxxi. 243; lxxxii. 356, 357). Larger crystals are obtained by adding chloride of sodium to the fused mixture. (Geuther and Forsberg, *ibid.* cxx. 268.—Schultze, *ibid.* cxxvi. 56.)

Those tungstates which are insoluble in water are also, for the most part, insoluble in dilute acids; by heating with concentrated acids, they are decomposed, with separation of tungstic acid (a character by which they are distinguished from the metatungstates); in the case of phosphoric acid, the precipitated tungstic acid dissolves in excess. At ordinary temperatures, tungstates are but imperfectly decomposed by concentrated acids, chiefly because a certain quantity of soluble tungstic acid is formed at the same time (p. 911). Alkaline tungstates in solution are decomposed by sulphuric, hydrochloric, nitric, and acetic acids, the greater part of the tungstic acid being separated as a yellow or white hydrate, which does not dissolve in an excess of the precipitating acid (except phosphoric acid); it dissolves, however, in a large quantity of water.

The precipitate obtained from cold solutions is frequently white, but gradually turns yellow even in the cold, and more quickly when heated. The composition of this white precipitate has been variously stated. Scheele regarded it as pure tungstic oxide, which however is not correct; according to Anthon and Riche, it is the dihydrate, $WO^3.2H^2O$; according to Marignac and others, it contains a basic tungstate, or it is a compound of tungstic acid with the precipitating acid. Whether the precipitate retains alkali or acid depends on the relative quantity of the precipitating acid, the dilution of the liquid, and perhaps also on the temperature.

Insoluble tungstates, whose bases are insoluble in alkaline carbonates, are decomposed by fusion with alkaline carbonate.

Solutions of alkaline tungstates give white precipitates with salts of *barium*, *strontium*, *calcium*, *aluminium*, *zinc*, *lead*, and *mercuricum*; yellowish-white with *mercurous nitrate*; peach-blossom-coloured with *chloride of cobalt*; bluish-white with *nitrate of copper*.—*Stannous chloride* forms a yellowish precipitate, which, when warmed with hydrochloric or sulphuric acid, turns blue, from formation of blue tungsten-oxide.

Ferrocyanide of potassium forms in solutions of alkaline tungstates, after addition of hydrochloric acid, a brown flocculent precipitate, soluble in pure water free from acid (distinction from metatungstates). Solutions of alkaline tungstates are not altered by *tincture of galls*, till an acid is likewise added, in which case a thick chocolate-coloured precipitate is formed. Tungstic acid, previously precipitated by acids, is also coloured brown by tincture of galls. Alkaline tungstates, ignited with *sal-ammoniac*, out of contact with the air, yield a tungstate of tungsten and the alkali-metal, together with a black substance, probably consisting of oxynitretamide of tungsten (p. 903). For the blowpipe-reactions of tungstates, and the reactions of soluble tungstates with zinc and with sulphide of ammonium, see p. 901.

Alkaline tungstates are sometimes used, in place of stannates, as mordants; they are also employed for rendering light fabrics non-inflammable (i. 1102).

TUNGSTATES OF ALUMINIUM.—The *neutral salt*, obtained by precipitating a neutral alkaline tungstate with alum, is white, flocculent, insoluble in water, but soluble in aqueous ammonia and in acids.—The *acid salt*, $Al^2O^3.7WO^3.9H^2O$ (at 100°), obtained by precipitation with an acid tungstate of alkali-metal is curdy, united in resinous lumps, and forms, when dry, a vitreous mass, having a conchoïdal fracture. (Lotz.)

TUNGSTATES OF AMMONIUM.—*a*. The *neutral salt* is formed by digesting tungstic acid or oxide with aqueous ammonia; on evaporating the solution, ammonia is given off, and an acid salt remains.

β. The *sesquiacid salt*, $2(NH^4)^2O.3WO^3.3H^2O = (NH^4)^4H^2(WO^4)^3.2H^2O$, sometimes crystallises from a very concentrated neutral solution of tungstic acid in ammonia, in warty crystals, which give off ammonia in contact with the air, leaving the following salt.

γ. $3(NH^4)^2O.7WO^3.6H^2O = (NH^4)^6H^8(WO^4)^7.2H^2O$.—This salt, to which Marignac assigns the formula $5(NH^4)^2O.12WO^3.11H^2O$, is obtained by slow evaporation of a cold solution of tungstic acid in ammonia (Lotz; Scheibler). It forms vitreous rhombic tables or prisms, acuminated with four faces resting on the edges of the prism. It has a biting bitter taste, reddens litmus slightly, dissolves in 26 to 28 pts. of cold water, is sparingly soluble also in aqueous ammonia, and insoluble in alcohol. The solution gives with nitric acid a white precipitate, which turns yellow gradually in the cold, immediately on boiling. When ignited in a close vessel, it leaves blue oxide of tungsten, and, when ignited in contact with the air, it leaves pure tungstic oxide, which retains the form of the crystals.

When the solution is evaporated by heat, small shining crystals are obtained (oblique, striated, rhombic prisms, according to Marignac), containing $3(NH^4)^2O.7WO^3.3H^2O$ [or, according to Laurent, $5(NH^4)^2O.12WO^3.4H^2O$; according to Marignac, $5(NH^4)^2O.12WO^3.5H^2O$]; they give off 2 at. water at 160°, and are reconverted into the hexhydrated salt by solution in water, and slow evaporation. (Scheibler.)

δ. An *ammonio-trihydric tetratungstate*, $(NH^4)^2O.3H^2O.4WO^3 = (NH^4)^2H^6(WO^4)^4$, is always formed (according to Riche) when a solution of ammonium-tungstate is left to evaporate slowly; and separates at ordinary temperatures in shining laminæ containing 3 at. water; at 40°—50°, in needles containing 2 at. water.

According to Wöhler and Anthon, an acid tungstate of ammonium is produced, with evolution of ammonia, when tungstate of potassium or sodium is boiled with sal-ammoniac. According to Laurent, Lotz, and others, the salt thereby formed is a double tungstate of ammonium and potassium or sodium.

ε. The salt, $2(NH^4)^2O.5WO^3.5H^2O = (NH^4)^4H^6(WO^4)^5.2H^2O$, crystallises on cooling from a solution of the salt *γ*, saturated while hot, in rhombic octahedrons, soluble in 26 to 29 pts. of water. On recrystallising it from water, thin nacreous needles are sometimes formed, containing $2[(NH^4)^3H^5(WO^4)^4].3H^2O$. (Marignac.)

TUNGSTATES OF BARIUM.—*a*. The *neutral salt*, $Ba''WO^4 = BaO.WO^3$, is obtained, in the anhydrous state, by precipitation from the solution of a neutral tungstate of alkali-metal. It is a white powder, insoluble in water, decomposed by the stronger acids, and also by alkaline carbonates, both in the wet and in the dry way. According to Scheibler, the precipitate formed by chloride of barium in a solution of neutral sodium-tungstate is always a mixture of different salts; but the neutral tungstate may be obtained pure by heating the metatungstate with hydrate of barium, or by dropping baryta-water into a moderately dilute and boiling solution of acid tungstate of sodium, $(3Na^2O.7WO^3)$, as long as the resulting precipitate is redissolved; the solution on cooling deposits a double salt, and the cooled mother-liquor yields, with excess of baryta water, a white bulky precipitate, which soon becomes dense and crystalline, and then forms spicular octahedrons of pure neutral barium-tungstate. The salt thus obtained, as well as that prepared from the metatungstate, contains $2Ba''WO^4.H^2O$.—The anhydrous salt is formed, in the dry way, by fusing together 2 pts. sodium-tungstate, 7 pts. barium-chloride, and 4 pts. sodium-chloride, and crystallises in colourless octahedrons, apparently isomorphous with the calcium-salt; they are decomposed by strong nitric acid at the boiling heat only. (Geuther and Forsberg.)

β. *Acid salt*, $3BaO.7WO^3.8H^2O$.—Obtained by precipitation from the acid sodium-salt. White; becomes anhydrous and yellowish by ignition. (Lotz.)

Sodio-baric tungstate, $\left.\begin{matrix}2BaO\\Na^2O\end{matrix}\right\}7WO^3.14H^2O$ (Scheibler), or $\left.\begin{matrix}2BaO\\3Na^2O\end{matrix}\right\}12WO^3.24H^2O$ (Marignac), separates in thin plates on cooling, from a hot solution of acid sodium-tungstate, after addition of baryta-water.

TUNGSTATE OF CADMIUM is obtained in colourless crystals, perhaps isomorphous with the calcium-salt, by fusing 4 pts. sodium-tungstate with 11 pts. cadmium-chloride and 16 pts. common salt (Geuther and Forsberg).—An *ammonio-cadmic tungstate*, $4(3CdO.7WO^3).[3(NH^4)^2O.7WO^3] + 35H^2O$, is obtained, as a white bulky precipitate, on mixing the solutions of acid ammonium-tungstate and cadmium-sulphate. (Lotz.)

Tungstate of Calcium, $Ca''WO^4$, or $CaO.WO^3$, occurs native, as **scheelite** or **tungsten**, in quadratic pyramids P, modified by the faces $2P\infty$ and $\frac{4P2}{2}$, the latter occurring hemihedrally. For P, the length of the principal axis is 1·0858; the angle P : P in the terminal edges = 107° 20′; in the lateral edges = 113° 51′. The crystals cleave indistinctly parallel to P, more distinctly parallel to $2P\infty$. The mineral likewise occurs reniform, with columnar structure, and massive granular. Hardness = 4·5 to 5. Specific gravity = 6 to 6·076. Lustre vitreous, inclining to adamantine. Colour white, inclining to yellow and brown. Streak white. Subtransparent to subtranslucent. Fracture uneven. Brittle. Scheelite is usually associated with crystalline rocks, and is found associated with tin-ore, topaz, fluor-spar apatite, or wolfram, in quartz. It occurs at Caldbeck Fell, near Keswick, in fine crystals; also in Bohemia, Saxony, Hungary, and Sweden, at Coquimbo in Chile, and in Monroe and Huntingdon counties, Connecticut.

Tungstate of calcium may be obtained in crystals, by fusing wolfram with excess of calcium chloride, and boiling out the soluble salts from the slowly-cooled mass (Manross, Ann. Ch. Pharm. lxxxi. 243)—also by heating the amorphous salt with lime in a stream of hydrochloric acid gas (Debray, *ibid.* cxxv. 97). The same salt is obtained by precipitation as a white powder. It is insoluble in pure water, and in acidulated water.

Tungstates of Chromium.—The *neutral salt*, $Cr^2O^3.3WO^3.13H^2O$, obtained by precipitation, is light-green, easily soluble in acids, and turns yellowish-grey in drying.—An *acid salt*, $Cr^2O^3.7WO^3.9H^2O$, obtained by precipitation from the acid ammonium-salt, is a light greyish-green powder, greenish straw-yellow after ignition. (Lotz.)

Tungstate of Cobalt, $CoWO^4$, is obtained in blue-greenish translucent crystals, by fusing 1 pt. sodium-tungstate, 2 pts. cobalt-chloride, and 2 pts. common salt. (Schultze.)

Tungstate of Copper.—The mixture obtained by fusing 2 pts. sodium-tungstate with 3 pts. cupric chloride and 4 pts. common salt, leaves, after treatment with dilute nitric acid, white translucent quadratic pyramids, on which yellowish-brown crystals are implanted. (Schultze.)

Tungstates of Iron.—*a. Ferric tungstate* is obtained, by precipitating ferric chloride with acid ammonium-tungstate, as a cream-coloured powder, which dissolves in tungstate of ammonium on boiling, and in ferric chloride even at ordinary temperatures. Ferric tungstate is also precipitated by ammonia from solution of ferric metatungstate, while an ammonio-ferric tungstate remains dissolved. The same double salt appears to be formed by the action of ammonia on the crude tungstic acid obtained by treating wolfram with nitromuriatic acid. Borck obtained in this manner a double salt containing $Fe^2O^3.5(NH^4)^2O.5WO^3 + 5H^2O$.

β. Ferrous tungstate, $Fe''WO^4$, is formed, by precipitating ferrous sulphate with acid tungstate of ammonium, as a brown precipitate, becoming darker when heated out of contact with the air. The same salt is obtained by fusing 1 pt. tungstate of sodium with 2 pts. ferrous chloride and 1 pt. common salt, in thick, deep black, highly lustrous, opaque crystals, having the form of native wolfram; they are non-magnetic, their powder is of a dark violet-brown colour, and specific gravity = 7·1 (Geuther and Forsberg). Debray, by igniting a mixture of tungstic oxide and ferric oxide in a stream of hydrochloric acid gas, obtained crystals of ferrous tungstate (together with crystals of magnetic iron-ore and tungstic oxide), exactly like those of native wolfram.

Ferroso-manganous Tungstate, $(Fe;Mn)''WO^4$, or $(FeO;MnO).WO^3$.—This is the composition of wolfram, the principal ore of tungsten, which occurs in trimetric crystals having the axes $a : b : c = 0·8231 : 1 : 0·851$. Angle $\infty P : \infty P$ (macr.) = 78° 55′; $\infty\bar{P}2 : \infty\bar{P}2$ = 44° 44′; $\breve{P}\infty : \breve{P}\infty$ (basal) = 80° 48; $\frac{1}{2}\bar{P}\infty : \frac{1}{2}\bar{P}\infty$ = 54° 40′. Observed combination $\infty P . \infty\bar{P}2 . \infty\breve{P}\infty . \frac{1}{2}\bar{P}\infty . \breve{P}\infty . P$. Cleavage parallel to $\infty\breve{P}\infty$. It also occurs lamellar, columnar, and massive granular, the particles being strongly coherent. Hardness = 5 to 5·5. Specific gravity = 7·1 to 7·55. Lustre submetallic. Colour dark-grey or brownish-black. Streak dark reddish-brown. Opaque, sometimes feebly magnetic. According to the proportions of iron and manganese in wolfram, the varieties may be included in three groups, represented by the formulæ $MnWO^4.3FeWO^4$, $MnWO^4.4FeWO^3$, and $MnWO^4.5FeWO^4$.

Wolfram is often associated with tin-ores; also with galena in veins traversing greywacke; also in quartz with native bismuth, tungstate of calcium, pyrites, galena, blende, &c. It occurs in Cornwall and Cumberland, on the island of Rona in the Hebrides, at Limoges in France, and at numerous localities in Saxony and Bohemia; also in the United States. The crystals from Zinnwald, Bohemia, are remarkable as hemitropes. (Dana, ii. 353.)

Geuther and Forsberg have obtained several crystallised tungstates of iron and manganese, by fusing tungstate of sodium with chloride of manganese and chloride of iron in various proportions.

TUNGSTATES OF LEAD.—The *neutral salt*, $Pb''WO^4$, or $PbO.WO^3$, occurs native as scheeletine, a mineral occurring in quadratic crystals, isomorphous with molybdate of lead (iii. 1039). Length of principal axis = 1·5692. Angle P : P in the terminal edges = 99° 42′, in the lateral edges = 131° 30′. The crystals are often indistinctly aggregated. Cleavage imperfect parallel to oP, still more imperfect parallel to P. Hardness = 2·75. Specific gravity = 7·87 to 8·13. Lustre resinous, subadamantine. Colour green, yellowish-grey, brown, and red. Streak uncoloured. Faintly translucent. The mineral occurs at Zinnwald in Bohemia, with quartz and mica; in Carinthia with molybdate of lead; and in Chile, probably near Coquimbo.

Neutral tungstate of lead is produced artificially, as a white powder, by precipitation from the neutral sodium-salt. By fusing tungstate of sodium with 4·7 pts. of chloride of lead in a closed crucible, a dark-green mass is obtained, having its cavities lined with colourless shining crystals of tungstate of lead. (Manross, Ann. Ch. Pharm. lxxxii. 357.)

The *acid lead-salt*, $3PbO.7WO^3.10H^2O$, is formed, on mixing acid ammonium-tungstate with a soluble lead-salt, as a white, flocculent, afterwards pulverulent precipitate, insoluble in water, dilute nitric acid, aqueous nitrate of lead, or tungstate of ammonium, but soluble in caustic soda. It gives off 7 at. water at 100°.

TUNGSTATES OF LITHIUM.—The *neutral salt* is prepared with tungstic acid and carbonate of lithium, either in the wet or in the dry way; and crystallises from the aqueous solution in oblique rhomboïdal prisms (C. Gmelin), or in octahedrons (Anthon), having a rough bitter taste and alkaline reaction, easily soluble in water.—The *acid salt*, $3Li^2O.7WO^3.19H^2O$, or $Li^6H^8(WO^4)^7.15H^2O$ (Scheibler), is prepared like the corresponding sodium-salt, avoiding an excess of tungstic acid, which would lead to the formation of a metatungstate. It crystallises in large monoclinic prisms and tables, permanent in the air, somewhat less soluble than the neutral salt; melts only at a high temperature, and solidifies to a porcelain-like mass on cooling.

TUNGSTATES OF MAGNESIUM.—Solutions of magnesium-salts are not precipitated by neutral tungstates of alkali-metal. By boiling magnesium-carbonate and tungstic oxide with water, a solution is obtained which on evaporation yields small shining scales, permanent in the air, having a harsh bitter taste, and easily soluble in water (Anthon).—The *neutral salt*, $Mg''WO^4 = MgO.WO^3$, is obtained by fusing 1 pt. sodium-tungstate, 2 pts. magnesium-chloride, and 2 pts. common salt, and boiling out the more soluble salts, in colourless, octahedral and prismatic crystals, which are gradually decomposed by heating with strong nitric acid: they are isomorphous with the neutral calcium-salt. (Geuther and Forsberg.)

Ammonio-magnesian Tungstates.—The salt $\left.\begin{matrix}2MgO\\(NH^4)^2O\end{matrix}\right\}7WO^3.10H^2O$ separates gradually, in small nacreous crystals, from a mixture of the hot concentrated solution of the tungstates of magnesium and ammonium.—Another double salt, $\left.\begin{matrix}3MgO\\2(NH^4)^2O\end{matrix}\right\}12WO^3.24H^2O$, separates, on cooling, as a crystalline powder, from a boiling solution of acid ammonium-tungstate mixed with sulphate of magnesium.

TUNGSTATES OF MANGANESE.—Manganous salts yield a white or yellowish precipitate with neutral or acid tungstate of ammonium.—The *neutral salt*, $MnWO^4$, prepared in the dry way like the magnesium-salt, forms thick, light garnet-brown, highly lustrous, rhombic crystals, of specific gravity 6·7; at the same time there are formed yellow needles having the same composition as the preceding (Geuther and Forsberg).—The *acid salt*, $3MnO.7WO^3.11H^2O$, is a gummy yellowish precipitate, which gives off only 3 at. water at 100°. (Lotz.)

The tungstates of iron and manganese have been already described (p. 907).

TUNGSTATES OF MERCURY.—*a. Mercuric Salts.*—A *basic salt*, $3HgO.2WO^3$, is obtained by precipitating a boiling solution of mercuric chloride with an insufficient quantity of potassic tungstate. It is a white heavy powder, insoluble in water.—An *acid salt*, $2HgO.3WO^3$, is obtained, as a white insoluble body, by precipitating a solution of neutral mercuric nitrate with neutral tungstate of potassium. Both these salts are decomposed by boiling alkalis, with separation of mercuric oxide, and leave tungstic oxide when ignited.—An *ammonio-mercuric tungstate*, $Hg''(NH^4)^2(WO^4)^2.H^2O$, is obtained, as a heavy white precipitate, on mixing mercuric nitrate with acid tungstate of ammonium.

β. Mercurous tungstate, $Hg^2O.WO^3$, or Hg^2WO^4 (Anthon), is formed, on adding mercurous nitrate to an alkaline tungstate, as a yellow precipitate, becoming dark-yellow when dry, insoluble in water, leaving tungstic oxide when ignited. The insolubility of this salt renders it available for the separation and estimation of tungstic acid.

Tungstate of Molybdenum is precipitated from a mixture of molybdic chloride and tungstate of ammonium, on addition of sal-ammoniac. After washing with sal-ammoniac, then with alcohol, and drying, it is a dark-purple body, permanent in the air, and easily soluble in water; ammonia, added to the aqueous solution, throws down an ammonio-molybdic tungstate. The solution of molybdic tungstate oxidises and becomes decolorised on exposure to the air, and deposits molybdic tungstic acid. (Berzelius.)

Tungstate of Nickel, $3NiO.7WO^3.14H^2O$, obtained on adding sulphate of nickel to acid tungstate of ammonium, as a light-green precipitate, which unites into lumps of the consistence of turpentine (Lotz). By fusing 1 pt. sodium-tungstate with 2 pts. nickel-chloride and 2 pts. common salt, the neutral tungstate of nickel, $NiWO^4$, is obtained in well-defined, brown, highly lustrous, translucent crystals, having the aspect of zinc-blende. (Schultze, Ann. Ch. Pharm. cxxxi. 56.)

Tungstates of Potassium.—These salts are formed by adding pulverised wolfram to about an equal weight of fused carbonate of potassium, continuing the heat for some time; on boiling the cooled and pulverised mass with water, evaporating the filtrate to dryness, and treating the residue with lukewarm water, the neutral salt dissolves, while the acid salt remains behind.

The *neutral salt*, K^2WO^4, or $K^2O.WO^3$, crystallises from a hot saturated solution on cooling, or on evaporation by heat, in anhydrous, thin, needle-shaped, hexagonal crystals, easily soluble in water, decrepitating when heated, and melting at a red heat (Marignac).—The *monohydrated neutral salt*, $K^2WO^4.H^2O$, is obtained by gradually adding 45 pts. of tungstic oxide to a concentrated solution of potassic carbonate heated to 60°—80°, and crystallises from the hot filtered solution on cooling, in needle-shaped, sometimes aggregated crystals. It has a rough and somewhat bitter taste, is easily soluble in water, insoluble in alcohol; on pouring alcohol on the aqueous solution, the salt crystallises at the surface of contact.—The *dihydrate*, $K^2WO^4.2H^2O$, crystallises by evaporation of the solution over oil of vitriol, at a temperature not above 10°, in large, shining, oblique, rhombic prisms or tables, which quickly effloresce in dry, and deliquesce in moist air.—The *pentahydrate*, $K^2WO^4.5H^2O$, crystallises, according to Anthon, in colourless six-sided prisms, but the conditions of its formation are not particularly stated.

The *acid salt* ($K^2O.2WO^3.2H^2O$, according to Anthon and Riche; $3K^2O.7WO^3.6H^2O$, according to Scheibler; $5K^2O.12WO^3.11H^2O$, according to Laurent and Marignac) is formed by adding tungstic acid to the neutral salt, in fusion or aqueous solution; or by treating this solution with any other acid; or by passing a stream of carbonic anhydride through it. The salt is then deposited as a crystalline powder, consisting of iridescent scales, while metatungstate of potassium remains in solution. The acid tungstate tastes like the neutral salt; it has an acid reaction, dissolves, according to Riche, in 46 pts. cold and 15 pts. boiling water; according to Marignac, in 71 pts. water at 20°. When, however, a saturated solution is prepared by boiling an excess of the salt with water for several days, the cooled solution contains 1 pt. of the salt, after one day, dissolved in 5·6 pts. water; after 26 days, in 11·9 pts. water; after 153 days, in 15·6 pts. water—this last degree of solubility remaining unaltered for six months (Marignac). The salt is insoluble in alcohol.

Tungstates of Silver.—An *acid argentic salt*, $Ag^2O.2WO^3$, or $Ag^2WO^4.WO^3$, is obtained by precipitating acid tungstates of alkali-metal with nitrate of silver, as a white anhydrous salt, insoluble in water, slightly soluble in acetic or phosphoric acids, more easily in ammonia. When ignited, it turns brown, and cakes together to a metallically lustrous mass.—An *acid argentous salt*, $Ag^4O.2WO^3$, is formed, according to Rautenberg, by the action of hydrogen on an ammoniacal solution of the argentic salt. It is a black, glittering, crystalline powder, which is decomposed by nitric acid, leaving tungstic oxide; potash dissolves the tungstic acid, leaving argentous oxide.

Tungstates of Sodium.—The *neutral salt*, Na^2WO^4, or $Na^2O.WO^3$, is prepared like the neutral potassium-salt. It crystallises in transparent, colourless, nacreous, rhombic tables or scales, containing $Na^2WO^4.2H^2O$, having a bitter taste and alkaline reaction, permanent in the air, soluble in 4 pts. of cold and 2 pts. of boiling water, insoluble in alcohol, and precipitated thereby from its aqueous solution. It may be recrystallised without decomposition. When heated to 200°, it gives off all its water, and becomes opaque; and at a temperature somewhat below redness, it melts to a transparent liquid, which solidifies in the crystalline form on cooling. This salt is sometimes used, in place of stannate of sodium, as a mordant in dyeing and calico-printing; also for rendering linen, cotton, &c., uninflammable (see COMBUSTION,

i. 1102). For the methods of preparing it on the large scale, see Richardson and Watts's *Chemical Technology*, i. [4], 48).

Acid salts.—The salt $3Na^2O.7WO^3$, according to Lotz and Scheibler ($5Na^2O.12WO^3$, according to Laurent and Marignac), is prepared similarly to the corresponding potassium-salt—namely, by fusing the neutral salt with a sufficient quantity of tungstic oxide, and boiling the product with water; or by boiling a solution of hydrate, carbonate, or neutral tungstate of sodium with tungstic oxide, and leaving the resulting solution to crystallise; or, again, by fusing wolfram with one-third of its weight of anhydrous carbonate of sodium. It crystallises from cold aqueous solutions with 16 at. water (Scheibler) [28 at. water, according to Marignac's formula], in large striated monoclinic prisms, of specific gravity 3·897 at 14°, sometimes flattened to six-sided tables. It has an astringent and, at the same time, sweet and bitter taste; reddens litmus; dissolves in 2·22 pts. water at 0°, and in 0·24 pt. at 100° (Scheibler); in about 12 pts. of cold water (Marignac). When water at 35°—40° is saturated with this salt, the cooled solution retains 1 pt. of salt dissolved in 9 pts. water; but gradually (in about 7 months), so much separates out that 1 pt. remains dissolved in nearly 12 pts. water. If the salt be boiled for some time with water, a solution is formed, which, when cold, contains, after one to twelve days, 1 pt. salt to 0·68—2·6 pts. water; and after seven months, 1 pt. salt to 9·7 pts. water (Marignac). The salt effloresces in dry air, gives off 12 at. water at 100°, and the rest at 300°, leaving the anhydrous salt, $3Na^2O.7WO^3$, of specific gravity 5·49, and still perfectly soluble in water. It melts at a red heat, and solidifies in the crystalline state on cooling; water then extracts from it the alkaline sesquiacid salt, $2Na^2O.3WO^3$, leaving the anhydrous tetratungstate, $Na^2O.4WO^3$, in the form of a laminar or scaly crystalline mass, having a nacreous lustre. This last-mentioned salt is quite insoluble in water; it does not melt at a moderate heat, but when more strongly heated, cakes together to a semifused mass, containing deep blue-green crystals (? of sodio-tungstous tungstate).

When the solution of the salt, $3Na^2O.7WO^3$, is evaporated by heat, crystals are obtained, containing smaller quantities of water than the above—viz., at 60°—80°, monoclinic crystals containing $3Na^2O.7WO^3.15H^2O$; and at 100°, shining octahedrons, containing $3Na^2.7WO^3.12H^2O$. or $5Na^2O.12WO^3.20H^2O$. (Marignac.)

A salt containing $2Na^2O.5WO^3.12H^2O$, is obtained, according to Forcher, in brilliant translucent crystals, by prolonged digestion of the neutral salt with water, or by saturating a warm solution of that salt with tungstic acid.

A *diacid salt*, $Na^2O.2WO^3.2H^2O$, is precipitated from the solution of the neutral salt by hydrochloric acid, as a crystalline powder (Rammelsberg, Pogg. Ann. xciv. 514).—The *anhydrous diacid salt*, $Na^2O.2WO^3$, or $Na^2WO^4.WO^3$, is formed by fusing 1 at. of the neutral tungstate with 1 at. tungstic acid, and is found in needles lining the cavities of the resulting crystalline mass. (Forcher.)

Ammonio-sodic Tungstates.—*a*. The salt, $\left.\begin{matrix}Na^2O\\2(NH^4)^2O\end{matrix}\right\}7WO^3.3H^2O$, crystallises in white nacreous scales, from a warm concentrated solution of 1 at. neutral sodium-tungstate, mixed with rather more than 1 at. chloride of ammonium.—*β*. $\left.\begin{matrix}3Na^2O\\12(NH^4)^2O\end{matrix}\right\}35WO^3.14H^2O$ separates in crystalline scales, on pouring a boiling solution of 1 at. sodium-tungstate into a boiling solution of 2 at. sal-ammoniac, a large quantity of ammonia being at the same time evolved.—*γ*. The salt $5\left(\begin{matrix}\frac{1}{4}Na^2O\\\frac{3}{4}(NH^4)^2O\end{matrix}\right).12WO^3.12H^2O$, or perhaps, in the pure state, $\left.\begin{matrix}Na^2O\\4(NH^4)^2O\end{matrix}\right\}12H^2WO^4$, crystallises in nacreous rhombic laminæ, on mixing the solutions of the acid tungstates of sodium and ammonium. It is soluble in water, but is resolved by recrystallisation into the ammonium- and sodium-salts.—*δ*. The salt $\left.\begin{matrix}2Na^2O\\3(NH^4)^2O\end{matrix}\right\}12WO^3.5H^2O$, is prepared similarly to the preceding, which it resembles. (Marignac.)

Bario-sodic tungstate has been already described (p. 906).

Potassio-sodic Tungstates.—A mixture of the tungstates of potassium and sodium deposits, first, crystals of the acid potassium-salt, then two double salts, viz., $\left.\begin{matrix}Na^2O\\4K^2O\end{matrix}\right\}.12WO^3.15H^2O$, in monoclinic crystals, and $5\left(\begin{matrix}\frac{3}{11}K^2O\\\frac{8}{11}Na^2O\end{matrix}\right).12WO^3.25H^2O$, in oblique rhombic octahedrons, and lastly, the acid sodium-salt. (Marignac.)

TUNGSTATES OF STRONTIUM.—The *neutral salt*, $SrWO^4$, is prepared like the barium-salt, which it resembles. By fusing 1 pt. of sodium-tungstate with 2 pts. strontium-chloride and 2 pts. common salt, it is obtained in white translucent crystals, having the form of native tungstate of lead. (Schultze.)

The *acid salt* ($SrO.2WO^3.4H^2O$ according to Anthon, $3SrO.7WO^3.4H^2O$ according to Lotz).prepared like the acid barium-salt, is white, insoluble in cold water, decomposed by acids, and becomes anhydrous when heated.

Tungstate of Thorinum.—Thorinum-salts give white flocculent precipitates with the neutral and acid tungstates of alkali-metal.

Tungstate of Tin.—A solution of ammonio-stannic chloride is precipitated by acid ammonium-tungstate, in white flocks, soluble in excess of the tin-salt, also in phosphoric, oxalic, and tartaric acids. (Lotz.)

Tungstate of Tungsten, $W^2O^5 = WO^2.WO^3$.—This is the blue oxide of tungsten, already mentioned as being formed by the reduction of tungstic oxide by zinc and hydrochloric acid, &c. It is likewise produced, as a fine blue powder, when tungstate of ammonium is heated to redness in a retort.

Tungstates of Uranium.—The *uranic salt* is a light-yellow precipitate, insoluble in water, but soluble in the stronger acids, and in ammonia (Berzelius).—An *acid uranous salt*, $2UO.WO^3.6H^2O$, is obtained, by precipitating uranous chloride with an acid tungstate of alkali-metal, as a brownish precipitate, soluble with green colour in hydrochloric acid. (Rammelsberg.)

Tungstate of Vanadium, precipitated by alkaline tungstates from vanadic salts, is brown, somewhat soluble in water, and oxidises in the air with formation of vanadic acid.

Tungstate of Yttrium, $YWO^4.2H^2O$, is a white pulverulent precipitate, slightly soluble in water. (Berlin.)

Tungstate of Zinc, $ZnWO^4$, is obtained, by fusing 1 pt. sodium-tungstate, 2 pts. zinc-chloride, and 2 pts. common salt, and boiling the mass with water, in colourless square prisms, with octahedral faces, probably isomorphous with the calcium-salt. (Geuther and Forsberg.)

Ammonium-zinc-tungstate, $\left.\begin{matrix}2ZnO\\(NH^4)^2O\end{matrix}\right\}7WO^3.3H^2O$, is obtained by precipitating sulphate of zinc with acid tungstate of ammonium, in small snow-white needles, which dissolve sparingly in boiling water, more easily on addition of ammonium-tungstate, zinc-sulphate, oxalic acid, tartaric acid, or phosphoric acid. (Lotz.)

Metatungstic Acid.

Soluble Modification of Tungstic Acid.—This acid is mostly produced in the decomposition of tungstates by the stronger acids at ordinary temperatures; also by the action of tungstic acid on tungstates. Pure metatungstic acid is obtained by decomposing a warm concentrated solution of barium-metatungstate with dilute sulphuric acid; the filtrate, evaporated over oil of vitriol in a vacuum, yields crystals, apparently quadratic octahedrons, of hydrated metatungstic acid, $H^2WO^4.7H^2O$, or $H^2O.WO^3 + 7aq$. (Scheibler), or more correctly, $H^2WO^4.3WO^3.31H^2O$, or $H^2O.4WO^3 + 31aq$. Forcher, by decomposing the lead-salt with sulphydric acid, and leaving the filtrate to evaporate, obtained metatungstic acid in sulphur-yellow crusts, apparently made up of octahedrons.

Metatungstic acid is very soluble in water; the solution has a sour and intensely bitter taste.

A solution	containing	2·79	per cent. WO^3	has a	specific gravity	of 1·0257	at 17·5°.
"	"	12·68	"	"	"	1·1275	
"	"	27·61	"	"	"	1·3274	
"	"	43·75	"	"	"	1·6343	

The solution may be boiled, and evaporated to a syrup over the water-bath, without alteration; but on further concentration by heat, ordinary yellow insoluble tungstic acid separates out suddenly.

Strong *sulphuric acid* added to a concentrated solution of metatungstic acid forms a white precipitate which disappears on addition of water. Aqueous metatungstic acid dissolves *zinc* and *iron*, with evolution of hydrogen, blue oxide of tungsten being formed at the same time.

A *colloïdal* modification of metatungstic acid is obtained by dialysing a 5 per cent. solution of sodium-tungstate mixed with a quantity of hydrochloric acid exactly sufficient to saturate the alkali contained in it. The solution remaining on the dialyser after a few days (amounting to 80 per cent. of the liquid used), has a bitter astringent taste, is not gelatinised by acids or salts even at the boiling heat, and when evaporated to dryness, leaves vitreous scales which adhere strongly to the porcelain dishes. They are colourless if the evaporation has taken place in a vacuum, do not lose their solubility by being heated to 200°, but, at a temperature near redness, are converted into insoluble tungstic oxide, with loss of 2·42 per cent. water. The dry soluble acid is rendered sticky by water, like gum. Its solutions exhibit, at 19°, the following specific gravities:

Quantity of tungstic oxide (WO^3) in 100 pts. .	5	20	50	66·5	79·8.
Specific gravity . . .	1·0475	1·2168	1·8001	2·596	3243.

(Graham, Chem. Soc. J. xvii. 318; Jahresb. 1864, p. 179.)

Metatungstates, $M^2O.4WO^3$, or $M^2WO^4.3WO^3$.—These salts have been examined chiefly by Scheibler (J. pr. Chem. lxxx. 204; Jahresb. 1860, p. 155); but the ammonium-salt, which was the first known, was discovered by Margueritte (Ann. Ch. Phys. [3], xvii. 475). They have the composition of quadracid tungstates, but the tungstic acid obtained from them is not ordinary tungstic acid, but the more soluble modification. They are formed from ordinary tungstates by addition of tungstic acid, or by abstraction of part of the base. The metatungstates of the alkali-metals are best prepared by boiling the solutions of the corresponding tungstates for some time with hydrated tungstic acid, $H^2WO^4.H^2O$, or by dropping an acid (phosphoric acid being the best adapted for the purpose) into the solution of an alkaline tungstate, as long as the tungstic acid separated in the first instance redissolves. The other metatungstates may be prepared from those of the alkali-metals by double decomposition, and very easily by decomposing the metatungstate of barium with soluble sulphates. The metatungstates may also be prepared by the direct combination of metatungstic acid with bases, or by its action on carbonates, nitrates, or chlorides, all of which it decomposes.

The metatungstates are for the most part soluble and crystallisable; some are very soluble, and leave amorphous gummy masses when evaporated; according to Marignac, they react nearly neutral, colouring litmus violet; they effloresce in dry air, and give off the greater part of their crystallisation-water below 100°. The metatungstates of the alkali-metals do not melt at a red heat, but merely bake together, decomposing at the same time, with formation of blue oxide. Their solutions do not precipitate the salts of the earth-metals, or of the heavy metals, excepting those of *lead* and *mercurosum*. They give no precipitate with *ferrocyanide of potassium*.—*Acids* added to the solutions of metatungstates do not precipitate either white or yellow tungstic acid.—*Zinc* and *hydrochloric acid* colour them blue, changing to reddish-violet (not to brown like the ordinary tungstates: Forcher). These reactions are sufficient to distinguish the metatungstates from the acid tungstates, with which they are in some cases isomeric. They are, however, easily reconverted into ordinary tungstates by addition of aqueous alkalis, the solutions being then precipitated by acids, as well as by the salts of the alkaline earth-metals and other metals.

Metatungstic acid precipitates the solutions of *organic bases* in flocks, and may therefore be used as a reagent for these bases; the solution of a metatungstate acidulated with a mineral acid, or ordinary tungstate of sodium mixed with excess of phosphoric acid, may be used for the purpose. This reaction with metatungstic acid is said to be even more delicate than that with phospho-molybdic acid, a distinct turbidity being produced by metatungstic acid in a solution containing not more than 1 pt. in 200,000 of quinine or strychnine.

Metatungstate of Ammonium, $(NH^4)^2W^4O^{13}.8H^2O$, or $(NH^4)^2O.4WO^3 + 8aq.$ according to Scheibler; $2(NH^4)^2W^4O^{13}.15H^2O$, according to Lotz.—This salt, discovered by Margueritte, is produced by boiling tungstate of ammonium, either alone, whereupon ammonia is given off, or with tungstic acid, which is dissolved. On evaporating the solution to a syrup, ordinary ammonium-tungstate separates out first, and the filtrate deposits the metatungstate in highly lustrous transparent octahedrons, which effloresce on exposure to the air. The salt is very soluble in water, melting at first at the bottom of the liquid, like phosphorus. The solution is strongly refractive, is not precipitated by hydrochloric or nitric acid, but when mixed with ammonia, and evaporated, yields crystals of ordinary acid tungstate, $3(NH^4)^2O.7WO^3$ (Lotz).—From the mother-liquor of the octahedral metatungstate just described, Margueritte obtained the salt $(NH^4)^2O.6WO^3 + 13aq.$, in well-defined crystalline laminæ. — The *potassium-salt*, $K^2W^4O^{13}.8H^2O$, obtained by boiling the tungstate with tungstic acid, crystallises in shining octahedrons resembling the ammonium-salt. The same solution yields slender needle-shaped crystals, which, however, are converted into the octahedral salt by recrystallisation; the salt appears therefore to be dimorphous (Scheibler).—The *sodium-salt*, $Na^2W^4O^{13}.10H^2O$, also crystallises in shining octahedrons, apparently regular, of specific gravity 3·84, and very efflorescent. One part of water at ordinary temperatures dissolves 10·69 pts. of these crystals, forming a solution of specific gravity 3·019; hot water dissolves the salt in all proportions. The salt gives off all its water at a heat much below redness, and if it has not been too strongly heated, still dissolves completely, though slowly, in water (Marignac). In other respects it behaves like the potassium- and ammonium-salts. Margueritte likewise mentions a salt containing $Na^2W^4O^{13}.4H^2O$.—The *lithium-salt* dries up over oil of vitriol to an amorphous mass.

Metatungstate of Barium, $BaW^4O^{13}.9H^2O$, is obtained by mixing the warm concentrated solutions of ammonium-metatungstate and barium-chloride, and, when purified by recrystallisation, forms large, shining, quadratic octahedrons, modified by the prismatic faces and the perpendicular end-faces. They have a specific gravity of 4·298, effloresce in the air, and give off 6 at. water at 100°; at a red heat the salt becomes yellow and insoluble. The crystals are decomposed by cold water into the insoluble triacid salt, $BaW^3O^{10}.6H^2O$, and free tungstic acid, which, however, recombine at the boiling heat. The metatungstate dissolves easily in boiling water; the solution yields metatungstic acid when decomposed by dilute sulphuric acid, and the other metatungstates (as those of magnesium, zinc, cadmium, cobalt, nickel, &c.), by double decomposition with soluble sulphates.—The *strontium-salt*, $SrW^4O^{13}.8H^2O$, obtained like the barium-salt, crystallises in quadratic octahedrons, modified by the faces oP and ∞P∞.—The *calcium-salt*, formed by decomposing chloride or carbonate of calcium with metatungstic acid, crystallises with difficulty.—The *magnesium-salt*, $MgW^4O^{13}.8H^2O$, forms shining, probably monoclinic crystals, permanent in the air.—The *glucinum-salt* is very soluble, but crystallises from a syrupy solution, in delicate deliquescent laminæ.—The *aluminium-salt* dries up to an amorphous mass.

Metatungstate of Cadmium, $CdW^4O^{13}.10H^2O$, forms shining quadratic octahedrons, permanent in the air.—The *cerous salt*, $CeW^4O^{13}.10H^2O$, prepared by decomposing cerous carbonate with metatungstic acid, crystallises in pale, lemon-yellow, monoclinic crystals, permanent in the air.—The *lanthanum-* and *didymium-salts* are also crystallisable.—The *cobalt-salt*, $CoW^4O^{13}.9H^2O$, crystallises in quadratic octahedrons; the *cupric salt*, $CuW^4O^{13}.11H^2O$, in laminæ and tables, probably belonging to the monoclinic system.—The *ferric salt* dries up to an amorphous mass; its solution, mixed with ammonia, yields a precipitate of ferric tungstate, while ammonio-ferric tungstate remains in solution.—The *ferrous salt*, prepared by dissolving iron in metatungstic acid, is crystallisable, but difficult to obtain pure. The solution, which has a fine blue colour, contains blue oxide of tungsten, as well as the ferrous salt.—The *lead-salt*, $PbW^4O^{13}.6H^2O$ (Lotz), or $PbW^4O^{13}.5H^2O$ (Scheibler), is obtained by precipitating a moderately concentrated solution of the acid, or the ammonium-salt, with acetate of lead, as a white flocculent salt, which dissolves in a large quantity of hot water, and crystallises by slow evaporation in slender silky needles, easily soluble in nitric acid.—The *manganous salt*, $MnW^4O^{13}.10H^2O$, forms beautiful, light-yellow, quadratic octahedrons, with perpendicularly truncated summits; they are permanent in the air.—The *mercurous salt*, $Hg^2W^4O^{13}.25H^2O$ (?), is obtained on adding mercurous nitrate to the free acid, or an alkaline metatungstate, as a white bulky precipitate, which shrinks considerably in drying, and assumes a lemon-yellow colour.—The *nickel-salt*, $NiW^4O^{13}.8H^2O$, forms monoclinic prisms and tables.—The *silver-salt*, $Ag^2W^4O^{13}.3H^2O$, is best prepared by mixing the boiling solutions of equivalent quantities of sodium-metatungstate and silver-nitrate, with addition of a few drops of nitric acid; the clear solution, on cooling, deposits the salt in waxy crusts, consisting of microscopic octahedrons. It dissolves easily in water, crystallises by evaporation over oil of vitriol, but remains as an amorphous mass when the solution is evaporated by heat.—The *zinc-salt*, $ZnW^4O^{13}.10H^2O$, is very soluble, and crystallises with difficulty.

Ethylic Metatungstate, probably $(C^2H^5)^2W^4O^{13}.3H^2O$, is produced by heating the silver-salt with ethylic iodide in sealed tubes, and remains, on distilling off the free ethylic iodide, exhausting with absolute alcohol, and evaporating quickly in a vacuum, as a thick viscid syrup, which slowly dries up, over oil of vitriol, to a greenish fissured mass. It is very unstable, and is instantly decomposed by water, yielding tungstic hydrate.

Ordinary tungstate of silver, heated with ethylic iodide, does not yield a tungstic ether.

TUNGSTEN, OXYBROMIDES OF. (See p. 899.)

TUNGSTEN, OXYCHLORIDES OF. (See p. 900.)

TUNGSTEN, PHOSPHIDES OF. Phosphorus and tungsten combine directly, but without incandescence, when finely-pulverised metallic tungsten is heated to redness in phosphorus-vapour. The resulting compound is a dull dark-grey powder, very difficult to oxidise, and containing W^3P^4.—Another compound, W^4P^2, is obtained in beautiful crystalline groups, like natural geodes, by reducing a mixture of 2 at. phosphoric and 1 at. tungstic anhydride, at a very high temperature, in a crucible lined with charcoal. The crystals are six-sided prisms, sometimes an inch long, having a steel-grey colour and strong lustre; specific gravity = 5·207. This compound is a good conductor of electricity, is scarcely oxidised when heated to redness, but burns with great splendour on charcoal in a stream of oxygen, or on fused chlorate of potassium; it is not attacked by any acid, not even by nitromuriatic acid. (Wöhler, Chem. Soc. J. v. 94.)

TUNGSTEN, SULPHIDES OF. The *disulphide*, WS^2, is formed when tungsten, or one of its oxides, is heated to redness with sulphur, or certain volatile sulphur-compounds. It is prepared by igniting tungsten or tungstic oxide with 6 pts. of cinnabar, or by passing the vapour of carbonic disulphide or sulphydric acid over tungstic oxide heated to redness in a porcelain tube; also by igniting the trisulphide in a close vessel (Berzelius and Borck). Riche prepares it by fusing equal parts of acid potassium-tungstate and sulphur in a crucible, and lixiviating the mass with water.

Disulphide of tungsten is (according to Berzelius) a greyish-white powder, acquiring, by pressure, a steel-grey colour and metallic lustre. According to Riche, it forms slender, soft, black, needle-shaped crystals, which soil the fingers like graphite. It is oxidised by ignition in the air, or in vapour of water, also when gently heated with nitric or nitromuriatic acid. It is not altered by fusion with cyanide of potassium. (Wöhler and v. Uslar.)

The *trisulphide*, or *Tungstic Sulphide*, WS^3, has hitherto been obtained only in the wet way. It is prepared by dissolving tungstic oxide in sulphydrate of ammonium or potassium, and precipitating with an acid; or by saturating an aqueous solution of alkaline tungstate with sulphydric acid, and precipitating with hydrochloric acid. It is black when dry, and yields a liver-coloured powder; dissolves slightly in cold water, more easily in boiling water; and is precipitated almost completely by sal-ammoniac and other salts, and by acids. When boiled with hydrochloric acid, the precipitate becomes denser and darker-coloured, ultimately black-blue, but remains soluble in water. It dissolves easily, especially when recently precipitated, in hydrate or carbonate of potassium, and in ammonia. When ignited, alone or with cyanide of potassium, it is reduced to the disulphide.

Trisulphide of tungsten unites readily with basic metallic sulphides, forming sulphur-salts called sulphotungstates, represented for the most part by the formula M^2WS^4, or $M^2S.WS^3$, analogous to that of the neutral tungstates. The sulphotungstates of the alkali-metals and alkaline earth-metals may be prepared by dissolving the trisulphide in the corresponding sulphydrates, or by treating the corresponding tungstates with sulphydric acid When trisulphide of tungsten is dissolved in a caustic alkali or an alkaline carbonate, a tungstate is formed, together with the sulphotungstate; and the resulting solution yields, with acids, a light red-brown precipitate of tungstic oxysulphide, which does not turn black when boiled with hydrochloric acid. The insoluble sulphotungstates of the earth-metals, and heavy metals, are obtained by precipitation, or by boiling a solution of alkaline sulphotungstate with the corresponding oxides.

The *ammonium-salt*, $(NH^4)^2WS^4$, separates from a concentrated solution in yellowish-red crystals; and the mother-liquor, when left to evaporate, deposits yellow rectangular tables. The salt is somewhat sparingly soluble; it decrepitates when heated, and when ignited out of contact of air, leaves tungstic sulphide in lumps having a metallic lustre.

The *potassium-salt*, K^2WS^4, separates from its aqueous solution, on evaporation, in anhydrous yellow crystals, or smooth, pale, four-sided red prisms, with dihedral summits, and is precipitated by alcohol in delicate cinnabar-red prisms. The aqueous solution, mixed with a small quantity of hydrochloric acid, yields, by evaporation, a black mass, consisting of an acid sulphotungstate, $K^2S.2WS^3$, or $K^2WS^4.WS^3$.—The aqueous solution of the neutral salt, boiled with cupric hydrate, yields cupric sulphide and tungstate of potassium. If the solution of the sulphotungstate contains also tungstate of potassium, or if the tungstate be fused with sulphur and the fused mass dissolved in water, the solution yields by evaporation lemon-yellow rectangular plates of the *oxysulphotungstate*, $K^2WS^2O^2.2H^2O$. A solution of 2 pts. potassium-sulphotungstate and 1 pt. potassium-nitrate, yields ruby-red transparent crystals of a double salt, containing $K^2WS^4.KNO^3$, which detonates like gunpowder when heated to commencing redness, yielding a pale-yellow mass, from which water extracts tungstate and sulphotungstate of potassium, leaving disulphide of tungsten.

The *sodium-salt*, Na^2WS^4, crystallises with difficulty from the aqueous, more easily from the alcoholic solution, by spontaneous evaporation. The crystals, when exposed to the air, soon become moist and yellow. There is also an acid salt, soluble in water and in alcohol.

The *barium-salt* is prepared by passing sulphydric acid gas through water in which tungstate of barium is suspended, and crystallises by evaporation in yellow, transparent, crystalline crusts. When tungstic sulphide is dissolved to saturation in protosulphide of barium, the yellow solution yields, by evaporation, a brown amorphous mass.—The *calcium-salt*, prepared like the barium-salt, is an amorphous mass, easily soluble in water and in alcohol; the *strontium-* and *magnesium-salts*, prepared in like manner, are also soluble in water and in alcohol; the former separates in lemon-yellow radiate crystals, the latter is uncrystallisable. The solutions of the calcium-, strontium-, and magnesium-salts take up an additional quantity of tungstic sulphide, and then leave, on evaporation, brown or brown-red amorphous masses.—The *manganous salt*, $Mn''WS^4$, also dissolves in water, forming a yellow solution.

The *cadmium-salt*, $Cd''WS^4$, and the *zinc-salt* are yellow precipitates, the latter separating gradually; the *cerium-salt* is also a yellow precipitate, which separates only after 24 hours.—The sulphotungstates of *cobalt*, *copper*, *lead*, and *nickel*, represented by the general formula $M''WS^4$, are brown or black-brown precipitates.—The *mercuric salt*, $Hg''NS^4$, is precipitated, on mixing the solutions of mercuric chloride and potassium-sulphotungstate in equivalent proportions, in orange-yellow flocks; with an excess of mercuric chloride, the precipitate is white; with an excess of the alkaline sulphotungstate, black.—The *mercurous salt*, Hg^2WS^4, is a black precipitate; the *silver-salt*, Ag^2WS^4, dark-brown.—The *stannous salt*, $Sn''WS^4$, is precipitated in brown flocks; the *stannic salt*, $Sn^{iv}(WS^4)^2.Sn^{iv}S^2$, in greyish-yellow flocks.—The *platinic salt*, $Pt^{iv}(WS^4)^2$, and the *auric salt*, $Au'''(WS^4)^3$, are black precipitates; the *bismuth-salt*, $Bi'''(WS^4)^3$, dark-brown, nearly black.—The *ferric salt*, $Fe'''(WS^4)^3$, is a dark-brown bulky precipitate. Ferrous salts do not precipitate a solution of potassium-sulphotungstate. (Berzelius.)

TUNGSTEN-METHYL. $W(CH^3)^4$. (Riche, Compt. rend. xlii. 203.—Cahours, Jahresb. 1861, p. 353.)—When tungsten is heated with methylic iodide to 240° in a sealed tube for several days, a viscid liquid is formed, from which ether-alcohol extracts iodide of tungsten-methyl, consisting, according to Riche, of $W(CH^3)^4I^2$, but, according to Cahours's analysis, of $W^{vi}\left\{\begin{matrix}(CH^3)^4\\ I^2\end{matrix}\right.$, a composition which is in accordance with the known atomicity of tungsten. This iodide crystallises in colourless tables, melts at 110°, and when agitated with recently-precipitated silver-oxide, is converted into oxide of tungsten-methyl, or tungstic oxytetramethide, $W^{vi}\left\{\begin{matrix}(CH^3)^4\\ O''\end{matrix}\right.$. This oxide dissolves in acids, forming uncrystallisable salts, remaining, when concentrated, as viscid liquids, from which the oxide is reprecipitated by alkalis.

Tungsten heated, in like manner, with *ethylic iodide* is scarcely attacked, only a few needles of tungstic oxyiodide being formed, which float about in the liquid. (Riche.)

TUNGSTIC COMPOUNDS. Compounds in which tungsten is hexatomic, viz., WCl^6, WO^3, $W(CH^3)^4I^2$, &c.

TUNGSTOSILICIC ACIDS. (Marignac, Ann. Ch. Phys. [4], iii. 5; Jahresb. 1864, p. 220.)—These are tetrabasic acids, containing both silicon and tungsten. Their names and formulæ, as given by Marignac, are as follows:

Silicoduodecitungstic or Silicotungstic acid . . .	$4H^2O.SiO^2.12WO^3$.
Tungstosilicic acid	$4H^2O.12WO^3.SiO^2$.
Silicodecitungstic acid	$4H^2O.SiO^2.10WO^3$.

They may be regarded as tungstates of silicon and hydrogen, the first two having the composition $H^8Si^{iv}O^6.12WO^3$, which is referable to that of an acid tungstate, $M^2O.2WO^3$.

The potassium- or sodium-salt of the first of these acids is produced by boiling gelatinous silica with acid tungstate of potassium or sodium, its formation probably taking place as represented by the equation:

$$\left.\begin{matrix}6(K^2O.2WO^3)\\ \text{or } K^{12}O^6.12WO^3\end{matrix}\right\} + Si(HO)^4 = K^8Si^{iv}O^6.12WO^3 + 4K(HO).$$

The resulting solution yields, with mercurous nitrate, a precipitate of mercurous silicotungstate; this, when decomposed by an exactly equivalent quantity of hydochloric acid, yields a solution of hydric silicotungstate, or silicotungstic acid; and the other silicotungstates, which are all soluble, are obtained by treating the acid with carbonates.

Silicodecitungstic acid is obtained as an ammonium-salt by boiling gelatinous silica with solution of acid tungstate of ammonium; and from this, the acid and its other salts may be obtained in the same manner as the preceding. The silicodecitungstates are very unstable, and the acid is decomposed by mere evaporation, depositing silica, and being converted into tungstosilicic acid, which is isomeric with silicotungstic acid, and likewise decomposes carbonates. All three of these acids are capable of exchanging either one half or the whole of their basic hydrogen for metals, thereby forming acid and neutral salts; silicotungstic acid also forms an acid sodium-salt, in which only one-fourth of the hydrogen is replaced by sodium.

Silicotungstic Acid, $4H^2O.SiO^2.12WO^3 = H^8SiW^{12}O^{42}$.—The concentrated solution of this acid, obtained as above, yields the acid, by spontaneous evaporation, in large, shining, colourless (or slightly yellowish), quadratic octahedrons, containing $H^8SiW^{12}O^{42} . 29H^2O$. They are combinations of P . ∞P∞ . oP, having the angle P : P in the terminal edges = 109° 9′; in the lateral edges = 110° 6′. They effloresce in contact with the air, begin to melt at 36°, and fuse completely, at 53°, to a liquid which yields another crystalline hydrate. At 100° they give off 25 at. water, another portion at a higher temperature, and the remainder at 350°; at this temperature, however, the acid retains its solubility; but at a stronger heat, it is converted into an insoluble mixture of silicic and tungstic anhydrides. The other hydrate, above mentioned as separating from the melted acid, contains $H^8SiW^{12}O^{42} . 22H^2O$, and is likewise formed when the acid separates from a solution containing hydrochloric or sulphuric acid. The crystals are combinations of a rhombohedron (R) with the basal end-face and a subordinate acute rhombohedron, whereby they acquire the character of cubo-octahedrons (R : R in the terminal edges = 88° 48′; oP : R = 124° 25′); they are distinguished from the octahedral crystals by their permanence in the air. Silicotungstic acid dissolves easily in water and in alcohol; the aqueous solution, saturated at 18°, contains 1 pt. of the octahedral acid to 0·104 pt. water, and has a density of 2·283. The alcoholic solution mixes with an equal volume of ether without turbidity; but, on adding more ether, the concentrated ethereal solution separates as a syrupy layer, which forms a clear solution in water, but becomes turbid and gives up the ether when heated. The same syrupy liquid (which does not contain any silicotungstic ethers), is obtained by exposing either the octahedral or the rhombohedral crystals to ether-vapour.

Silicotungstates.—Silicotungstic acid is a strong acid, decomposing carbonates, and easily forming double salts. The salts are all soluble in water, excepting the mercurous salt, and almost all crystallise well. They are not altered by boiling with hydrochloric acid. Caustic alkalis and alkaline carbonates throw down silicic acid from their solutions; the precipitate formed by ammonia redissolves at the boiling heat. When heated to redness, they glow slightly, and leave a residue containing free tungstic anhydride.

Silicotungstate of Aluminium is obtained by dissolving aluminium-hydrate in silicotungstic acid, or by adding the latter to a solution of aluminium-chloride, in large regular octahedrons containing $\overset{\prime\prime}{Al}{}^4H^{12}Si^3W^{36}O^{126}.87H^2O$, or $2Al^2O^3.6H^2O.3(SiO^2.12WO^3) . 87aq$. The cold solution is rendered turbid by addition of ammonia, but becomes clear again when warmed, and yields, after evaporation of the excess of ammonia, an octahedral double salt, containing $2Al^2O^3.9(NH^4)^2O.3(SiO^2.12WO^3) . 75aq$.

Ammonium-salts.—The *octammonic* or *tetrabasic salt*, $(NH^4)^8SiW^{12}O^{42}.16H^2O = 4(NH^4)^2O.SiO^2.12WO^3.16aq.$, is produced by saturating the acid with ammonia, or by prolonged boiling of a solution of silicodecitungstate of ammonium, and remains, on leaving the solution to evaporate, in opaque white nodules. By boiling with hydrochloric acid, it is converted into the *tetrammonic salt*, $(NH^4)^4H^4SiW^{12}O^{42}.6H^2O$. Both these salts, when heated with ammonia, yield sparingly soluble acid tungstate of ammonium, which separates, and silicodecitungstate of ammonium, which crystallises on evaporation.

Barium-salts.—On mixing a solution of silicotungstic acid with carbonate of barium till a permanent precipitate of neutral salt is produced, the clear liquid yields, on evaporation, monoclinic prisms of the *dibarytic salt*, $\overset{\prime\prime}{Ba}{}^2H^4SiW^{12}O^{42}.14H^2O$, which, by prolonged contact with the mother-liquor, are converted into a more highly hydrated efflorescent salt, containing $\overset{\prime\prime}{Ba}{}^2H^4SiW^{12}O^{42}.14H^2O$. On adding chloride of barium to an excess of a hot solution of sodium-silicotungstate, a double salt, $\overset{\prime\prime}{Ba}{}^3Na^2SiW^{12}O^{42}.28H^2O$, separates, on cooling, in crystals apparently having the form of rhombic octahedrons. They are decomposed by continued washing, leaving a pulverulent, nearly insoluble tetrabasic salt.

Calcium-salts.—The *dicalcic* or *acid salt*, $\overset{\prime\prime}{Ca}{}^2H^4SiW^{12}O^{42}.22H^2O$, crystallises from a syrupy solution in very large, shining, rhombohedral crystals, R . oP, permanent in the air. The warm solution takes up carbonate of calcium, but the resulting neutral salt is not crystallisable.

Magnesium-salts.—The *acid salt*, $\overset{\prime\prime}{Mg}{}^2H^4SiW^{12}O^{42}.16H^2O$, forms triclinic prisms, permanent in the air.—The *neutral salt* is not crystallisable.

The *mercurous salt*, $Hg^8SiW^{12}O^{42}$, is a heavy yellow precipitate, insoluble in water, very slightly soluble in dilute nitric acid.

Potassium-salts.—*a.* The *neutral salt*, $K^8SiW^{12}O^{42}.14H^2O$, prepared by boiling gelatinous silica with acid potassium-tungstate, crystallises, on cooling from the hot filtered solution, in hard granular crusts, which may be purified by recrystallisation; the crystals look like cubes, but exhibit double refraction. The salt dissolves in 10 pts. water at 18°, and in less than 3 pts. boiling water.—β. The *tetrapotassic salt*, $K^4H^4SiW^{12}O^{42} . 16H^2O$, crystallises, on evaporating a solution of the neutral salt mixed with hydrochloric acid, in large, colourless, shining, hexagonal prisms, with pyramidal summits, $\infty P . P$. Angle $P : P$, terminal = 144° 46'; lateral = 74° 30; prismatic faces longitudinally striated. The crystals effloresce slightly in the air, and at 100° give off their water of crystallisation, together with 1 at. of the basic water. They dissolve in 3 pts. water at 20°.—γ. A solution of the tetrapotassic salt mixed with hydrochloric acid, then evaporated and left to cool, deposits, first a pulverulent very acid salt, then crystals of the tetrapotassic salt; but when these two salts are left for some time in the mother-liquor, they both disappear, and another salt is deposited in monoclinic prisms containing $2K^3H^5SiW^{12}O^{42} . 25H^2O^2$; they are decomposed by solution in water, the liquid, when evaporated, yielding, first crystals of rhombohedral silicotungstic acid, then the salt β, and lastly the salt γ.

The *silver-salt*, $Ag^4H^4SiW^{12}O^{42} . 7H^2O$, separates as a crystalline precipitate when carbonate of silver is dissolved in silicotungstic acid, or when this acid is added to a solution of silver-nitrate. It is slightly soluble in water, easily soluble in dilute nitric acid.

Sodium-salts.—α. The *neutral salt*, $Na^8SiW^{12}O^{42} . 7H^2O$, is prepared like the neutral potassium-salt, and crystallises by spontaneous evaporation in slender needle-shaped crystals. The saturated solution contains 0·21 pts. water to 1 pt. of the salt, and has a specific gravity of 3·05 at 19°.—β. The *tetrasodic salt*, $Na^4H^4SiW^{12}O^{42}$, crystallises from a solution of the neutral salt mixed with hydrochloric acid, with amounts of water varying according to circumstances. If the crystallisation takes place at 40°—50°, or from a solution containing hydrochloric acid, at ordinary temperatures, triclinic tabular crystals are obtained, containing 11 at. water. A pure, concentrated, aqueous solution deposits, at ordinary temperatures, nacreous, efflorescent, triclinic prisms with 18 at. water. A hot concentrated solution deposits, on cooling, first crystals of the 11-hydrated salt, afterwards triclinic prisms differently modified and containing a different amount of water, and finally the 18-hydrated salt. When nitric acid is used, in place of hydrochloric acid, in the preparation of the tetrasodic salt, the mother-liquor yields on concentration a double salt, $4NaNO^3.3(Na^4H^4SiW^{12}O^{42}. 13H^2O)$, in hygroscopic triclinic prisms, mostly twins with the combination-face $\infty\breve{P}\infty$. —γ. The *disodic salt*, $Na^2H^6SiW^{12}O^{42}.14H^2O$, crystallises, on evaporating a solution of the tetrasodic salt, mixed with sulphuric or silicotungstic acid, in triclinic tabular crystals, very much like those of the tetrasodic salt deposited from a warm solution. This salt decomposes when dissolved in water.

Tungstosilicic Acid, $H^8W^{12}SiO^{42} = 4H^2O.12WO^3.SiO^2$ (Marignac).—This acid, isomeric with silicotungstic acid, is produced when a solution of silicodecitungstic acid is evaporated to dryness by heat, and crystallises from a solution filtered from silica, and evaporated to a syrup, in triclinic prisms, exhibiting the dominant combination $\infty{}'P . \infty P'_{,} . \infty\breve{P}\infty . oP$, with domes and hemipyramids subordinate. The crystals deliquesce in damp air. They melt below 100° in their water of crystallisation, and then dry up with intumescence. At 200°, the residue crumbles to a fine powder, which contains 2 at. water, and redissolves in water, with rise of temperature; the acid does not lose its solubility even when heated above 300°. It is also easily soluble in alcohol, and behaves to ether like silicotungstic acid (p. 915).

The tungstosilicates are obtained by saturating the acid with carbonates. Some of them are uncrystallisable, and others are distinguished from the corresponding silicotungstates by their crystalline form, degree of solubility, and amount of water of crystallisation; but there is no characteristic reaction by which the two isomeric acids can be distinguished one from the other.

Tungstosilicate of aluminium, $2Al^2O^3.6H^2O.3(12WO^3.SiO^2).75H^2O$, crystallises from a syrupy solution of gelatinous alumina in tungstosilicic acid, in triclinic prisms, resembling the calcium-salt, and frequently united in twins by the face $\infty{}'_{,}P$.

The *ammonium-salt* has not been obtained of definite composition.

Barium-salt.—On saturating a solution of tungstosilicic acid with baryta-water, a precipitate is formed, which redissolves in the acid liquid on stirring, until more than 2 at. baryta have been added, after which it unites into a layer, oily when warm, resinous in the cold, and drying up in contact with the air to a vitreous mass, consisting of the neutral barium-salt, $Ba^4SiW^{12}O^{42} . 9H^2O$, or $4BaO.12WO^3.SiO^2 . 9aq$. It becomes glutinous again in contact with water, and after prolonged contact crumbles to a powder, which in the air-dried state contains $4BaO.12WO^3.SiO^2 . 27aq$.

The *acid calcium-salt*, $2CaO.2H^2O.12WO^3.SiO^2 . 20aq.$, forms triclinic crystals, $\infty{}'_{,}P . \infty P'_{,} . \infty\breve{P}\infty . oP$ &c., tabular from predominance of $\infty\breve{P}\infty$; it is hygroscopic in moist air. Sometimes another salt, $5CaO.3H^2O.2(12WO^3.SiO^2).47aq.$, was obtained in small shining triclinic crystals, less hygroscopic than the former.

Potassium-salts.—The *neutral salt*, $4K^2O.12WO^3.SiO^2.20aq.$, forms small ill-defined prismatic crystals belonging to the trimetric system.—The *tetrapotassic acid salt*, $2K^2O.2H^2O.12WO^3.SiO^2.7aq.$, likewise crystallises in the trimetric system, and in short hard prisms. $\infty P . \bar{P}\infty . oP$, having the angle $\infty P : \infty P = 101° 0'$; $\infty P . \bar{P}\infty = 131° 0'$; $\bar{P}\infty : \bar{P}\infty$ (basal) $= 116° 28'$; or in friable, nacreous, six-sided tables, arranged in radiate groups.

Sodium-salts.—The *acid salt*, $2Na^2O.2H^2O.12WO^3.SiO^2.10aq.$, forms large rhombohedrons, $R - \frac{1}{2}R$, having the terminal angle $R : R = 87° 0'$.—The *neutral salt* was not obtained in the crystalline form.

Silicodecitungstic acid, $H^8SiW^{10}O^{36}$, $= 4H^2O.SiO^2.10WO^3$, is obtained by heating gelatinous silica with acid tungstate of ammonium, precipitating with mercurous nitrate, or better with silver-nitrate, in the cold, and decomposing the precipitate, after thorough washing, with hydrochloric acid, carefully avoiding an excess. On evaporating the filtered solution in a vacuum, at ordinary temperatures, the acid remains as a transparent yellow glass, containing $H^4SiW^{10}O^{36}.3H^2O$. On exposure to the air, it rapidly absorbs water, splits into fragments, and finally deliquesces. With alcohol and ether, it behaves like silicotungstic acid. The aqueous solution may sometimes be repeatedly evaporated without alteration, but, in most cases, it easily splits up into gelatinous silica and tungstosilicic acid. It does not precipitate the salts of calcium, magnesium, lead, or aluminium; with *nitrate of silver*, it forms a heavy yellowish precipitate, easily soluble in dilute nitric acid; with *mercurous nitrate* a white precipitate, slightly soluble in nitric acid.

Most of the silicodecitungstates are difficult to obtain in the pure state, on account of their great solubility.—The *ammonium-salt* contains $(NH^4)^8SiW^{10}O^{36}.8H^2O$.—The *neutral potassium-salt* appears to crystallise with 17 at. water; the *acid salt*, $K^4H^4SiW^{10}O^{36}$, with 8 at. and 10 at. water; an *ammonio-potassic salt*, $K^4(NH^4)^3HSiW^{10}15H^2O$, was likewise obtained.—The *barium-salt*, $Ba^4SiW^{10}O^{36}$, is obtained, by adding the acid to an excess of barium-chloride solution, as a viscid insoluble precipitate, which, when dried in the air, contains 22 at. water.—The *silver-salt*, dried at 100°, contains $Ag^8SiW^{10}O^{36}.3H^2O$.

TUNGSTOSO-TUNGSTIC COMPOUNDS. Compounds intermediate in composition between tungstous and tungstic compounds: *e.g.*, $W^2Cl^{10} = WCl^4.WCl^6$; $WO^5 = WO^2.WO^3$.

TUNGSTOUS COMPOUNDS. Compounds in which tungsten is quadri-equivalent: *e.g.*, WCl^4, WO^2, WS^2, &c.

TUNICIN. A substance isomeric, and perhaps identical, with cellulose, $(C^6H^{10}O^5)$, occurring in the mantle of Ascidia, and separated therefrom (from the mantle of Cynthia, for example) by successive treatment with water, alcohol, ether, acids, and alkalis. It then remains as a colourless mass, exhibiting the structure of the original substance (Schmidt, Ann. Ch. Pharm. liv. 318).—Berthelot (Compt. rend. xlvii. 227) boils the mantles, first with strong hydrochloric acid, then with potash-ley of specific gravity 1·28, and washes the residue thoroughly with distilled water.

Tunicin exhibits most of the characteristic properties of cellulose, and its insolubility in various liquids; but it is more stable, not being altered by nitric, hydrochloric, or acetic acid, or strong potash-solution, even after prolonged boiling; neither is it blackened by fluoride of boron. In fuming nitric or sulphuric acid, it deliquesces to a colourless liquid; and if the liquid obtained with sulphuric acid be boiled for some time with water, the resulting solution will be found to contain glucose, or a similar sugar.

TURBETH. Syn. with TURPETH.

TURGITE. A name applied by Hermann to a massive variety of brown hæmatite, $2Fe^2O^3.H^2O$, occurring near the River Turga, in the Ural; it appears to be identical with Breithaupt's *hydrohæmatite* from Siebenhitz, near Hof, in Bavaria. (Handw. d. Chem. viii. 1043.)

TURMALINE. Syn. with TOURMALINE (p. 875).

TURMERIC. *Curcuma. Radix Curcumæ. Terra merita.*—The root of *Amomum Curcuma*, a plant cultivated in India and Java. It contains, according to Pelletier and Vogel, a strong-smelling volatile oil, gum, a yellow colouring-matter (*curcumin*), a brown colouring-matter, starch, cellulose, and a small quantity of calcium-chloride. It is used for dyeing wool and silk; but the colour, though a fine yellow, is not durable. It is also employed in pharmacy for colouring certain ointments, and (especially in India) as an ingredient of curry-powder and other condiments.—Alcoholic tincture of turmeric, or paper stained with the aqueous or alcoholic solution, is used as a test for alkalis, and for boric acid (i. 639).

The root of *Canna speciosa*, a plant of frequent occurrence in West Africa, is said to be exactly similar to East Indian turmeric-root, in taste, smell, and chemical reactions (Daniell, Pharm. J. Trans. xix. 258.)

TURNBULL'S BLUE. Ferrous ferricyanide, prepared by precipitating a ferrous salt with ferricyanide of potassium. (See CYANIDES OF IRON, ii. 244.)

TURNERITE. A silicate of aluminium, iron (ferricum), calcium, and magnesium, occurring at Mont Sorel in Dauphiné, and at Tavetsch, in yellow monoclinic crystals, having an adamantine lustre and conchoïdal fracture. Axes $a : b : c = 1 : 0{\cdot}921696 : 0{\cdot}95844$. Angle $b : c = 102° 42'$; $\infty P : +P = 141° 23'$; $+P : +P\infty = 143° 44'$; $\infty P : \infty P\infty = 131° 58'$. In the mineral from Tavetsch, the combination $\infty P . \infty P\frac{1}{3} . \infty P2 . \infty P\infty . oP . +P\infty . [\frac{1}{3}P\infty] . [\frac{1}{4}P\infty] . [P\infty] . P . 2P2 . +\frac{1}{3}P . +\frac{1}{2}P . -\frac{1}{3}P$ was observed. In that from Dauphiné, the faces $-P\infty$ and $[2P\infty]$ likewise occur. (G. v. Rath, Jahresb. 1863, p. 824.)

TURNER'S YELLOW: also called *Patent Yellow*. Oxychloride of lead, $Pb^4Cl^2O^3$. (iii. 545).

TURNIP. See BRASSICA (i. 654).

TURPENTINE. *Terebenthina. Térébenthine. Terpentin.*—This term is applied to several oleoresins exuding from coniferous trees; also to the semifluid resin of *Pistacia Terebinthus*, a tree belonging to the terebenthaceous order. To obtain the turpentine, incisions are made in the bark of the trees, and the resinous juice, which exudes chiefly during the summer, is collected; it is then rendered more fluid by warming with water, and strained through straw-filters, to free it from needles, bark, and other extraneous substances.

The several varieties of commercial turpentine, obtained from fir- and pine-trees, are more or less viscid solutions of resins in a volatile oil, the proportions of these constituents varying according to the source and age of the turpentine. Some kinds are clear and homogeneous; others are more or less turbid, holding in suspension granulo-crystalline masses, which gradually settle to the bottom.

American turpentine, obtained chiefly from *Pinus australis*, and German turpentine from the Scotch fir (*Pinus sylvestris*), are yellowish, viscid, granular liquids, having a strong aromatic odour, and pungent bitter taste; they become clear when warmed, are highly inflammable, and burn with a very smoky flame. These turpentines consist of volatile oil and colophony (i. 1087); and on boiling them with water, the volatile oil goes off with the steam, while the resin remains, intimately mixed with small quantities of oil and water, forming a dingy yellow turbid mass, called "boiled turpentine," which is brittle when cold, but becomes soft and plastic when heated. At a stronger heat, the water and the remaining portion of volatile oil are given off, and the colophony remains as a transparent resin, more or less coloured, according to the degree of heat to which it has been exposed. Colophony was formerly said to be a mixture of two isomeric acid resins, pinic and sylvic acids (iv. 649, 650; v. 648); but the recent investigations of Maly (Ann. Ch. Pharm. cxxxii. 249; Jahresb. 1864, p. 408), have shown that it consists mainly of abietic anhydride, $C^{44}H^{62}O^4$, which, when treated with aqueous alcohol, takes up water, and is converted into abietic acid, $C^{44}H^{64}O^5$.*

French turpentine (from *Pinus maritima*) resembles American turpentine in appearance, odour, and taste. It hardens with calcined magnesia more readily than any other kind of turpentine.

Strasburg turpentine is a clear non-granular liquid, obtained from the silver fir (*Abies pectinata*), and from the spruce-fir (*Abies excelsa*). The turpentine from the former of these trees is mobile, yellow, has a pleasant odour of lemon, and a sharp bitter taste. That from the spruce-fir is dark-yellow, has a strong balsamic odour, and sweetish aromatic taste. The resinous portion of both these turpentines contains abietic acid, together with two indifferent resins, one (abietin) soluble in absolute alcohol, the other insoluble. The water with which these turpentines are distilled to get off the volatile oil, is said to contain succinic acid.

Venice turpentine—*Terebenthina venetia*, s. *laricina*, from the larch (*Larix europæa*)—is said to be contained in peculiar sacs in the upper part of the stem, and to be obtained by puncturing them. It is a ropy liquid, colourless, or brownish inclining to green, having a somewhat unpleasant odour, and bitter taste. According to

---

* The formula given for abietic acid at p. 1 vol. i. belongs properly to sylvic acid, which is produced from abietic acid by the action of dilute sulphuric acid. The acid formerly designated as sylvic acid is regarded by Maly as impure hydrated abietic acid, and the so-called pinic acid as abietic anhydride.

Unverdorben (Pogg. Ann. xi. 27), it contains, in the fresh state, two oils of different degrees of volatility, the less volatile being easily resinised; also two acid resins, a neutral resin, and succinic acid.

Hungarian turpentine, which flows from incisions in the branches of *Pinus Pumilio*, is a clear, yellowish, mobile liquid, having an aromatic taste and odour.—Carpathian turpentine, from *Pinus Cembra*, resembles the last, but has a bitter taste.—Canadian turpentine, or Canada balsam, from *Abies balsamea*, has been already described under BALSAMS (i. 492).

Cyprian, Syrian, or Chio turpentine, obtained in Chio from *Pistacia terebinthus*, and in Syria from *P. vera*, is either clear and colourless, or, perhaps from age, or from want of care in collecting it, viscid, turbid, and yellowish-green; it has an odour of fennel and elemi, and an aromatic taste like that of mastic. It dissolves completely in ether, and partially in alcohol, leaving a glutinous residue.

Ordinary turpentine and Venice turpentine are used in medicine, both externally as ingredients of salves and plasters, and internally in the form of electuaries or pills; for the last-mentioned purpose, the turpentine is thickened by addition of magnesia; boiled turpentine (p. 920) is also made into pills. Many kinds of turpentine are also used for varnishes or similar purposes.

TURPENTINE, BOILED. See p. 919.

TURPENTINE CAMPHOR. A term applied sometimes to the solid monohydrochlorate, sometimes to the solid hydrates of turpentine-oil (p. 923).

TURPENTINE GALL-NUTS. *Gallæ pistacinæ. Carobe de Juda*; formerly designated as *Folliculi pistacinæ*. Pea-shaped or horny excrescences, occurring in August on the branches of the turpentine-chestnut (*Pistacia Terebinthus*), and formed by the puncture of an insect (*Cephis Pistaciæ*). They are reddish-brown, having an aromatic turpentine-like odour, and similar taste. They contain resin, volatile oil, tannin, and gallic acid. The ash contains a potassium-salt, silica, and lime. (Martius, Ann. Ch. Pharm. xxi. 179.—Guibourt, Pharm. Centr. 1844, p. 409.)

TURPENTINE, OIL OF. $C^{10}H^{16}$.—A volatile oil contained in the wood, bark, leaves, and other parts of pines, firs, and other trees belonging to the coniferous order, and separable therefrom by distillation with water. It is usually prepared by distilling crude turpentine (p. 919), either alone or with water. It was formerly supposed that all the volatile oils thus obtained, and having a composition represented by the formula $C^{10}H^{16}$, were identical in physical and chemical properties; but recent investigations, especially those of Berthelot,[*] have shown that the turpentine-oils obtained from different sources exhibit considerable diversities in their physical and more especially in their optical properties; further, that most kinds of turpentine-oil are mixtures of two or more isomeric or polymeric hydrocarbons, differing in physical and sometimes also in chemical properties. These modifications are often produced by the action of heat and of chemical reagents during the purification of the oil.

The following varieties of turpentine-oil are distinguished:—

1. French turpentine-oil, obtained from the French or Bordeaux turpentine of *Pinus maritima*.
2. English turpentine-oil, from the turpentine collected in Carolina, and other southern states of the American Union, from *Pinus australis* and *P. Tæda*.
3. German turpentine-oil, chiefly from the turpentine of *Pinus sylvestris*, *P. nigra*, and *P. rotundata*.
4. Venetian turpentine-oil, from Venice turpentine, the produce of *Larix europæa*.
5. Templin or Pine-cone oil, obtained from the cones of *Pinus Pumilio*, and, in some parts of Switzerland, from those of *Abies pectinata*.

Related to the true turpentine-oils are also two volatile oils, likewise obtained from coniferous plants—viz., oil of juniper from *Juniperus communis*, and oil of savine from *Juniperus Sabina*.

The several varieties of turpentine-oil, when purified by repeated rectification with water, are colourless mobile liquids, having a peculiar aromatic but disagreeable odour. They are insoluble in water, slightly soluble in aqueous alcohol, miscible in all proportions with absolute alcohol, ether, and carbonic disulphide. They dissolve iodine, sulphur, phosphorus, and many organic substances which are insoluble in water, such as fixed oils and resins, and are therefore used for making varnishes.

The diversities of character exhibited by turpentine-oils of different origin, relate chiefly to the specific gravity, boiling-point, and optical rotatory power. It must be remembered, however, that the substances designated as turpentine-oils are often mixtures of several substances, so that these properties may vary even in turpentine-oils of the same origin, according to the modes of preparation and purification adopted.

---

[*] Ann. Ch. Pharm. lxxxiii. 105; lxxxviii. 345; cx. 367; Suppl. ii. 226; further, *Traité de Chimie organique*, ii. 692, 716—753. For references to earlier researches on turpentine-oil, see Gmelin's *Handbook*, xiv.

The specific gravity of turpentine-oils usually varies from 0·86 to 0·88. Their boiling-points are always near 160°. The rotatory power varies considerably: *e.g.*—

For English turpentine-oil . . $[\alpha] = +18{\cdot}6^{\circ}$
„ French „ . . $[\alpha] = -35{\cdot}4^{\circ}$
„ Venetian „ . . $[\alpha] = -5{\cdot}2^{\circ}$
„ Templin-oil . . . $[\alpha] = -76{\cdot}9^{\circ}$

The rotatory power of turpentine-oil is independent of that of the turpentine from which it is prepared. Thus, for example, English turpentine-oil is dextrorotatory, whereas the turpentine from which it is prepared is lævorotatory. Venice turpentine turns the plane of polarisation to the right, whereas the volatile oil distilled therefrom turns it to the left, &c.

The principal constituents of French and English turpentine-oils have been more particularly examined by Berthelot (*loc. cit.*).

French turpentine-oil consists mainly of a hydrocarbon, $C^{10}H^{16}$, called by Berthelot terebenthene. This substance cannot, however, be readily obtained from the commercial oil, in which it is contaminated with numerous products of transformation; but it may be prepared in a state of purity, by neutralising French turpentine with an alkaline carbonate, and distilling it, first over the water-bath, and then in a vacuum. By this treatment, all transformation of the product by heat, or by reagents, is avoided, and a hydrocarbon is obtained of constant physical character. Terebenthene thus prepared is a liquid of specific gravity 0·864, boiling at 161°, and having a specific rotatory power $= -42{\cdot}3^{\circ}$.

Australene, or Austraterebenthene, the chief constituent of English turpentine-oils, prepared in like manner from the turpentine of *Pinus australis*, is also a liquid, having the same specific gravity and boiling-point as terebenthene, but a specific rotatory power $= +21{\cdot}5^{\circ}$.

French turpentine-oil likewise contains an isomeric hydrocarbon, terepentilene, boiling below 180°, and another called parterebenthene, polymeric with terebenthene, which boils at about 250°. English turpentine-oil contains, besides australene, an isomeric body called austrilene. (Berthelot.)

Decompositions.—1. Turpentine-oil absorbs the *oxygen* of the air, becoming thicker, and ultimately resinous; at the same time, carbonic, acetic, and formic acids are produced. In this gradual oxidation, as in all slow combustions, part of the atmospheric oxygen is converted into ozone: hence turpentine-oil, after prolonged exposure to the air, always contains oxygen and ozone in solution, together with a continually increasing quantity of an oxygenated compound. When turpentine-oil containing water is exposed for some time to the sun's rays, in a large flask filled with oxygen, which is renewed from time to time, a hydrated oxide of turpentine-oil, $C^{10}H^{16}O.H^2O$, is deposited on the sides of the vessel, in stellate groups of long needles, soluble in hot water, also in alcohol and in ether. (Sobrero, Ann. Ch. Pharm. lxxx. 106.)

2. *Chlorine* is absorbed by turpentine-oil, with evolution of heat, sometimes sufficient to produce inflammation. When paper soaked in rectified turpentine-oil is introduced into a vessel filled with chlorine, the turpentine takes fire, and a quantity of black smoke is produced, together with white fumes of hydrochloric acid.—*Bromine* acts in a similar manner.—*Iodine* is dissolved by turpentine-oil, forming at first a green solution, which afterwards becomes hot, and gives off hydriodic acid. When a considerable quantity of iodine is suddenly brought in contact with turpentine-oil, explosion frequently ensues. Turpentine-oil distilled with *chloride of lime* and *water*, yields chloroform.

3. Turpentine-oil is rapidly attacked by *nitric acid*, the concentrated acid often setting it on fire. On evaporating the solution to dryness, and then distilling, the distillate contains nitrobenzene (Schiff, Ann. Ch. Pharm. cxiv. 201). If the nitric acid solution be precipitated with water, and the separated resin distilled with potash, toluidine passes over, together with other products (Chautard, *ibid.* lxxxviii. 340). In both these reactions, therefore, products are formed belonging to the class of aromatic compounds. When turpentine-oil is boiled for some time with moderately strong nitric acid, numerous products of decomposition are obtained, the formation of which has not yet been explained: nitrogen, carbonic oxide, carbonic dioxide, and hydrocyanic acid are evolved as gases; formic, acetic, propionic, and butyric acids distil over; and the residue contains oxalic acid, terebic acid (p. 723), camphretic acid,

(described under PYROCAMPHRETIC ACID, iv. 757), terephthalic acid, (p. 723), terebenzic acid (p. 723), and terechrysic acid (p. 725).

5. Turpentine-oil heated with *litharge* takes up a large quantity of oxygen, yielding formate and terebentate of lead. On washing the precipitate with alcohol, suspending it in water, decomposing it with sulphydric acid, exhausting the remaining solid substance with alcohol, and leaving the alcoholic solution to evaporate, white crystals are obtained, consisting of terebentic acid, $C^8H^{14}O^4$. (Weppen, Ann. Ch. Pharm. c. 253.)

6. The action of other acids, salts, &c., which combine directly with turpentine-oil, or merely convert it into isomeric or polymeric modifications, will be considered further on.

Compounds of Turpentine-oils with Hydrochloric, Hydrobromic, and Hydriodic Acids.

Hydrochlorates.—The terebenthenes, subjected to the action of hydrochloric acid gas, yield a mixture of crystallisable and liquid monohydrochlorates, $C^{10}H^{16}.HCl$. When they are left for some time in contact with fuming hydrochloric acid, or when their ethereal or alcoholic solution is saturated with hydrochloric acid, water then added, and the liquid left exposed to the air, a crystallisable dihydrochlorate, $C^{10}H^{16}.2HCl$, is produced; sometimes, also, unstable compounds of several hydrochlorates are obtained. The dihydrochlorates are likewise produced by the action of hydrochloric acid upon the hydrates of turpentine-oil, and by that of the chlorides of phosphorus on terpin-hydrate and terpin (p. 923).

The monohydrochlorates are optically active, producing rotation to the right or left, according to the nature of the terebenthene from which they have been formed: thus for the solid monohydrochlorate of terebenthene, $[\alpha] = -32{\cdot}2^\circ$; for that of australene, $[\alpha] = +11{\cdot}7$.—The dihydrochlorate is optically inactive.

The several varieties of turpentine-oil, inasmuch as they consist essentially of terebenthenes, likewise react with hydrochloric acid in the manner just described; indeed, most of the published statements respecting the hydrochlorates of turpentine-oil relate to products which have been prepared from turpentine-oils of unknown origin.

Solid Monohydrochlorate, $C^{10}H^{16}.HCl$.—This compound, also called artificial camphor, was discovered by Klein, in 1803. It is prepared by saturating rectified turpentine-oil with hydrochloric acid, keeping the liquid cool, pressing the crystals which separate after some hours, and recrystallising them from hot alcohol, or precipitating the alcoholic solution with water. It forms white crystals or crystalline flocks; by slow sublimation, it may be obtained in tufts of needles or shining laminæ. It resembles common camphor in appearance and in odour, and sublimes easily at ordinary temperatures. It melts at 115°, and boils, with partial decomposition, at 16·5°. It is insoluble in water, easily soluble in alcohol (especially at the boiling heat), and in oil of turpentine. At ordinary temperatures, it is very stable, not giving up its chlorine even to silver-salts; but when heated, it is decomposed by water and alcohol (at 160°), though not completely. The hydrochlorate is likewise decomposed when heated with salts, the decomposition sometimes requiring rather a high temperature. The product is always a hydrocarbon of the formula $C^{10}H^{16}$—viz. camphene, inactive camphene, or camphilene (pp. 924, 925).

Liquid Monohydrochlorate, $C^{10}H^{16}.HCl$ (sometimes called hydrochlorate of terebene).—Produced, together with the solid monohydrochlorate, by the action of hydrochloric acid gas on turpentine-oil, the proportion of the liquid hydrochlorate being greater as the temperature at which the reaction takes place is higher. To purify it, the liquid decanted from the solid hydrochlorate is cooled to −10°, in order to remove the portion of solid hydrochlorate still remaining in solution, then warmed for some time in the water-bath, treated with chalk, dissolved in twice its volume of alcohol, decolorised with animal charcoal, precipitated with water, and dried over chloride of calcium. It is a colourless, optically active oil, of specific gravity 1·017. It is decomposed by heating with salts, or with bases, but the hydrocarbon (camphilene, p. 925), which is the direct product of the decomposition, has not been further examined. By distillation over quicklime, it yields the so-called terpilene (p. 925).

Dihydrochlorate, $C^{10}H^{16}.2HCl$.—Produced when turpentine-oil is left for some time in contact with very strong hydrochloric acid (Berthelot); when terpin, terpin-hydrate, or terpinol is saturated with hydrochloric acid gas, or treated with the fuming acid (Deville, Ann. Ch. Pharm. lxxi. 351.—List, *ibid.* lxxvii. 369); also when terpin or terpin-hydrate is acted upon by a chloride of phosphorus (Oppenheim, *ibid.* cxxix. 149). When a solution of turpentine-oil in alcohol, ether, or acetic acid is saturated with hydrochloric acid, easily decomposible compounds of the dichlorhydrate with the solid or liquid monohydrochlorate are produced; and on adding water, and leaving the liquid for some time in contact with the air, crystals of the dihydrochlorate are obtained.

The dihydrochlorate forms rhombic tables, insoluble in water, easily soluble in boiling alcohol. It is slowly decomposed by boiling with water or alcohol, quickly by boiling with alcoholic potash-solution, yielding terpinol.

Hydrobromates.—Hydrobromic acid acts on turpentine-oil in the same manner as hydrochloric acid, forming a crystallisable and a liquid monohydrobromate, $C^{10}H^{16}.HBr$. A crystallisable dihydrobromate, $C^{10}H^{16}.2HBr$, melting at 42°, is produced by the action of phosphoric pentabromide on turpentine-oil. When hydrobromic acid gas is passed into a solution of turpentine-oil in acetic acid, a liquid compound of the two hydrobromates, $C^{10}H^{16}.HBr + C^{10}H^{16}.2HBr$, is formed; when exposed to the air, it yields crystals of the dihydrobromate. (Oppenheim, Ann. Ch. Pharm. cxxix. 149.)

Hydriodates.—Gaseous hydriodic acid does not appear to form a solid compound with turpentine-oil. The product, which is liquid and easily decomposible, appears to be a mixture of two hydriodates, one corresponding with the solid, the other with the liquid monohydrochlorate.

Terpin, treated with iodide of phosphorus (PI^3 or PI^2), yields the easily decomposible dihydriodate, $C^{10}H^{16}.2HI$, which crystallises from ethereal solution, in colourless hexagonal tables melting at 48°. (Oppenheim.)

Hydrates of Turpentine-oil.

The terebenthenes unite with water in several proportions, yielding the following compounds:

$C^{10}H^{16}.3H^2O$	$C^{10}H^{16}.2H^2O$	$C^{10}H^{16}.H^2O$	$2C^{10}H^{16}.H^2O.$
Terpin-hydrate.	Terpin.	Terpentin-hydrate.	Terpinol.

Terpin-hydrate, $C^{10}H^{16}.2H^2O$. aq. (also called *Turpentine-camphor* and *Hydrate of Turpentine-oil*), is frequently deposited in crystals from turpentine-oil containing water; its production is favoured by the presence of an acid. To prepare it, 8 vols. turpentine-oil are mixed with 2 vols. nitric acid and 1 to 6 vols. alcohol; and the mixture is frequently shaken during the first few days, then left to itself in shallow vessels for several weeks. Brown crystals are thereby formed, which must be pressed, and then recrystallised from boiling water, with addition of animal charcoal.

Terpin-hydrate usually crystallises in large rhombic prisms; it dissolves sparingly in cold, easily in boiling water, easily also in alcohol and ether. At 100° it melts, gives off its water of crystallisation, and is converted into terpin. The same change takes place on exposing the crystals to air dried over oil of vitriol.

Terpin, $C^{10}H^{16}.2H^2O$, melts at 103°, and solidifies in the crystalline state on cooling. It sublimes at about 150°, in slender needles. It is dissolved with red colour by *strong sulphuric acid*, and converted into turpentine-oil. The same change takes place on boiling the terpin with *dilute acids*, heating it to 100° with *chloride of zinc*, or to 160°—180° with *chloride of calcium, strontium*, or *ammonium*. Terpin, or terpin-hydrate, subjected to the action of gaseous or aqueous *hydrochloric acid*, or of either of the *chlorides of phosphorus*, is converted into the crystallised dihydrochlorate, $C^{10}H^{16}.2HCl$. Terpin, distilled with *phosphoric anhydride*, yields terebene and colophene (p. 924). When vapour of terpin is passed over *soda-lime*, heated to 400°, terebentilic acid (p. 723) is produced. Heated with *acetic* or *butyric acid*, or with *benzoic chloride*, it yields terebene and polyterebenes (p. 924). When heated with *acetic anhydride* to 140°, for not too long a time, it yields a compound containing $C^{10}H^{16}.C^2H^4O^2.H^2O$, regarded by Oppenheim as an acetic ether, $\left.\begin{matrix}(C^{10}H^{18})''\\ C^2H^3O\\ H\end{matrix}\right\}O^2$. This compound boils at 140°—150°, under a pressure of 2 centimetres of mercury.

Terpinol, $2C^{10}H^{16}.H^2O$. (Wiggers, Ann. Ch. Pharm. lvii. 247.—List, *ibid.* lxvii. 367.—Oppenheim, cxxix. 155.)—Produced when terpin is boiled or distilled with dilute hydrochloric or sulphuric acid; also when the dihydrochlorate of terebenthene is boiled with water, alcohol, or alcoholic potash. It is a colourless, strongly refracting oil, having a pleasant odour of hyacinths, slightly soluble in water, and optically inactive. Specific gravity = 0·852. It boils at about 168°, but suffers partial decomposition at the same time, and in such a manner, that the first portions of the distillate contain less oxygen than the later portions. It forms with hydrochloric acid the crystallisable dihydrochlorate, $C^{10}H^{16}.2HCl$, and may be reconverted into terpin by assumption of water.

Terpentin-hydrate, $C^{10}H^{16}.H^2O$. *Liquid Turpentine-camphor.*—This compound is sometimes obtained in the preparation of terpin, either together with the latter, or forming the only product. It is a liquid insoluble in water; boils, apparently without decomposition, at 200°—220°, and in presence of water appears to be converted, under circumstances not exactly understood, into terpin. It is optically active; $[\alpha] = -42{\cdot}4°$. When treated with hydrochloric acid, it yields the crystallisable dihydrochlorate, $C^{10}H^{16}.2HCl$. (Deville, Ann. Ch. Pharm. lxxi. 348.)

Molecular Transformations of Turpentine-oil.

I. By heat.—Terebenthene (p. 922) when carefully prepared, may be distilled, and even heated considerably above its boiling-point, without alteration; but towards 250°, it begins to undergo a change, the boiling-point rising, the rotatory power diminishing, and the product becoming more easily oxidisable in contact with the air; this alteration goes on the more rapidly as the temperature is higher. The product consists of one isomeric and several polymeric modifications of terebenthene.

The isomeric modification, called terepyrolene, resembles austrapyrolene, but has not been particularly examined. The chief product is the polymeric modification metaterebenthene, $C^{20}H^{32}$. It is a yellowish viscid liquid, boiling at about 360°, and of specific gravity 0·913. It forms, with hydrochloric acid, the liquid compound $C^{20}H^{32}.HCl$.

Australene (p. 921), heated for several hours to 250°, is converted into the isomeric body, austrapyrolene, boiling at 177°, and having a specific gravity of 0·847, and specific rotatory power = −11°. It smells like lemon-oil, is more readily oxidisable than australene, and forms a solid hydrochlorate, $2C^{10}H^{16}.3HCl$, which has a specific rotatory power of −14·6°. By continued heating, the polymeric body, metaustraterebenthene, is produced, very much like metaterebenthene, having a specific gravity of 0·91, and boiling at about 360°; its specific rotatory power is smaller than that of australene, and of opposite sign.

II. By reagents.—Many substances possess the power of converting terebenthene into isomeric or polymeric modifications. Some act even at ordinary temperatures, others only with the aid of heat. Many produce the transformation in a very short time; others act slowly, and never produce complete transformation. In some cases very small quantities of the reagent are sufficient to produce complete transformation, but frequently large quantities are required. The most energetic reagent is *fluoride of boron*. 1 pt. of this substance instantly converts 160 pts. terebenthene, with great rise of temperature, into polymeric optically inactive modifications, boiling above 300°.—*Sulphuric acid* likewise acts in the cold, but less energetically; 1 pt. of this acid converts 4 pts. terebenthene into an isomeric and a polymeric modification.—Weak mineral acids (like *boric acid*), and several organic acids (e.g., *acetic, oxalic, tartaric,* and *citric acids*), act upon terebenthene at 100°; but the action is very slow, and not complete, even after 50 or 60 hours.—*Chloride of zinc*, at 100°, acts in a similar manner.—*Fluoride* and *chloride of calcium*, and even the *chlorides of the alkali-metals*, act in like manner, but very feebly; the transformation takes place, however, more quickly in presence of these substances than under the influence of heat alone.

The products of these transformations are the same in all cases, viz.:

α. Terebene, an isomeric modification.—This substance is best prepared by the action of strong sulphuric acid on terebenthene or australene, and may therefore also be obtained from turpentine-oil. The process consists in mixing the turpentine-oil with $\frac{1}{20}$th of its weight of strong sulphuric acid, leaving the liquid to stand for twenty-four hours, then decanting it from the sediment, and distilling; repeating the process till the product no longer acts on polarised light; then washing with water and carbonate of sodium, drying over chloride of calcium, and rectifying.

Terebene is a liquid having the odour of thyme-oil, a specific gravity of 0·864, boiling at 156°, optically inactive. With hydrochloric acid, it forms a liquid compound, $2C^{10}H^{16}.HCl$, and similar compounds with hydrobromic and hydriodic acids.

β. A liquid optically inactive hydrocarbon, boiling at 250°, and probably consisting of sesquiterebene, $C^{15}H^{24}$.

γ. Diterebene, Metaterebene, or Colophene, $C^{20}H^{32}$.—Produced, together with terebene, in the process above described. It is an oil, having an aromatic odour, a blue iridescence, optically inactive, of specific gravity 0·94, boiling at 310°—315°. It absorbs hydrochloric acid gas, but does not appear to form a definite compound with it. Chlorine converts it into a resinous mass, from which alcohol extracts a compound crystallising in yellow needles, and probably consisting of a substitution-product, $C^{20}H^{28}Cl^4$. (See i. 1086.)

δ. Various polyterebenes, $(C^{10}H^{16})^n$.—Optically inactive liquids, of continually increasing viscidity, and boiling at temperatures between 360° and a low red heat.

III. By combination with hydrochloric acid or water, and decomposition of these compounds.

The solid monohydrochlorates of turpentine-oil, subjected to the action of very weak reagents, yield hydrocarbons, $C^{10}H^{16}$, designated by Berthelot as **camphenes**.[*] The three following are known:—

1. **Terecamphene.**—Produced by heating the solid hydrochlorate, prepared from French turpentine-oil, to 200°—220°, for a considerable time, with stearate of potassium or dry soap. The product, purified by recrystallisation from alcohol, is solid and crystallisable, with the aspect of camphor. It melts at 45°, and boils at about 160°. Specific rotatory power $[\alpha] = -65°$. It forms only one compound with hydrochloric acid, namely, a solid monohydrochlorate, $C^{10}H^{16}.HCl$, whose specific rotatory power is $+32$; that is to say, equal and opposite to that of the solid monohydrochlorate of terebenthene.

2. **Austracamphene.**—Obtained from English turpentine-oil in the same way as terecamphene is obtained from the French oil. It resembles terecamphene in all its properties, excepting in its optical rotatory power, which is $[\alpha] = +22°$. It forms a solid monohydrochlorate, having a specific rotatory power of $-5°$.

3. **Inactive Camphene.**—This is a solid hydrocarbon, produced by treating turpentine-oil, in the manner above described, with stearate of barium, or better with benzoate of sodium: it resembles terecamphene in every particular, excepting in its relation to polarised light. It forms a solid monohydrochlorate, which is likewise inactive.

Camphilene.—This name is given by Berthelot to a hydrocarbon (not yet examined), which is produced by the action of potassium-stearate or other weak reagents on the liquid monohydrate of terebenthene.

The same name (also *Dadyl*) is applied to a hydrocarbon (evidently a product of the transformation of camphene), formed by distilling the solid monohydrochlorate of turpentine-oil several times over quicklime, or in the state of vapour over lime heated to 190°—195°. It is a limpid aromatic liquid, of specific gravity 0·87, boiling at 156°, and without action on polarised light. According to Laurent, it forms, with chlorine, the compound $C^{10}H^{15}Cl.HCl$, which, when treated with alcoholic potash, yields chlorocamphilene, $C^{10}H^{15}Cl$; and this again unites with chlorine, forming the compound $C^{10}H^{14}Cl^2.HCl$, &c.: hence it would appear that camphilene reacts with chlorine in the same manner as ethylene.

Terpilene.—An inactive hydrocarbon, produced by the action of weak reagents on the solid dihydrochlorate, $C^{10}H^{16}.2HCl$.

Terebilene is a hydrocarbon obtained by distilling the liquid monohydrochlorate of turpentine-oil with quicklime or with potassium; also by distilling the corresponding hydriodate with potash. It smells like terebene, and is optically inactive. Specific gravity = 0·843. Boiling-point = 134°.

Substitution-products of Turpentine-oils.

Chlorine forms, with turpentine-oil, a liquid having a camphorous odour, and turning the plane of polarisation to the right, even when it has been prepared from lævo-rotatory turpentine-oil. It appears to be a mixture of tetrachlorinated turpentine-oil and tetrachloroterebene.

When chlorine is passed over the solid monohydrochlorate of turpentine-oil, a yellow liquid is formed, consisting of $C^{10}H^{12}Cl^4.HCl$, and easily resolved into hydrochloric acid and tetrachlorinated turpentine-oil, $C^{10}H^{12}Cl^4$. The latter is crystalline, melts at 110°—115°, and decomposes at a higher temperature. It is optically inactive.

Terebene also forms substitution-products with chlorine, chiefly tetrachloroterebene.

Bromine acts on turpentine-oil and terebene similarly to chlorine, forming chiefly tetrabrominated products.

The products of the action of chlorine on camphilene have already been mentioned.

TURPENTINE-VARNISHES. Solutions of resins in oil of turpentine.

TURPETH or **TURBITH MINERAL.** An old name for basic mercuric sulphate, $HgSO^4.2HgO$ (p. 605). Sulphate of tetramercurammonium, $(N^2Hg^4)SO^4.2H^2O$, is sometimes called *ammoniacal turpethum*.

TURPETH or **TURBITH ROOT.** The root of *Convolvulus Turpethum*, or *Ipomæa Turpethum*, a plant indigenous in India and Australia. It has a disagreeable sweetish taste, and contains, according to Boutron-Charlard (J. Pharm. viii. 131), a volatile oil, fat, a yellow colouring-matter and a drastic resin. This resin constitutes about 4 per cent. of the root, and contains about $\frac{1}{20}$th of its weight of a substance soluble in ether, the remaining $\frac{19}{20}$ths consisting of **turpethin**. (Spirgatis.)

[*] The term "camphene" is commonly used as a generic name for the hydrocarbons, $(C^{10}H^{16})$, (see i. 724). If it be restricted to the meaning above given, the entire group may be designated as **terpenes**.

TURPETHIC ACID. $C^{34}H^{60}O^{18}$. (Spirgatis, J. pr. Chem. xcii. 97: Jahresb. 1864, p. 591.)—An acid produced by the action of bases on turpethin, $C^{34}H^{56}O^{16}$. When turpethin is dissolved in warm baryta-water, the baryta removed by sulphuric acid, the excess of this acid by lead-hydrate, the latter by sulphydric acid, and the filtrate evaporated, turpethic acid remains as an amorphous yellowish mass, easily soluble in water, having a strong acid reaction, and a bitter somewhat sour taste. It forms two barium-salts, containing $C^{34}H^{58}Ba''O^{18}$ and $C^{34}H^{58}Ba''O^{18}.C^{34}H^{60}O^{18}$. It is resolved by mineral acids into glucose and turpetholic acid.

TURPETHIN. $C^{34}H^{56}O^{16}$. (Spirgatis, *loc. cit.*)—A purgative resin, isomeric with jalapin and scammonin, extracted from the root of *Ipomœa Turpethum* (*vid. sup.*). To prepare it, the root is exhausted with cold water: the dried residue is treated with alcohol, the alcoholic extract concentrated by distillation; the residue mixed with water; and the brown-yellow mass thereby precipitated is repeatedly boiled with water, then dried and shaken up four or five times with ether, and repeatedly precipitated by ether from solution in absolute alcohol.

Turpethin thus prepared is a brownish-yellow inodorous resin, gradually exciting a sharp bitterish taste, and strongly irritating the mucous membranes of the mouth and nose when pulverised. It dissolves easily in alcohol, like jalapin, but is distinguished from that substance by its insolubility in ether. It melts at about 183°, and dissolves slowly in strong sulphuric acid, forming a red liquid. When treated with alkalis, baryta-water for example, it takes up 2 at. water, and is converted into turpethic acid. Under the influence of mineral acids, it is redissolved into glucose and turpetholic acid:

$$C^{34}H^{56}O^{16} + 6H^2O = 3C^6H^{12}O^6 + C^{16}H^{32}O^4.$$

TURPETHOLIC ACID, $C^{16}H^{32}O^4$, separates, in the reaction just described, as a yellowish-white granular conglomerate; and after washing with water, and repeated crystallisation from dilute alcohol, with addition of animal charcoal, forms a white mass, made up of slender microscopic needles. It is inodorous, has an irritating taste and acid reaction, dissolves easily in alcohol, less easily in ether, melts at about 88°, and decomposes at a stronger heat, like jalapinolic acid (iii. 440) giving off a white fume which strongly irritates the eyes and nose.—*Turpetholate of Sodium*, $C^{16}H^{31}NaO^4$, is a white mass, having a silky lustre, and exhibiting, under the microscope, sharply defined rhombic plates, with angles of about 55° and 125°.—The *barium-salt*, $C^{32}H^{62}Ba''O^8$, is amorphous. (Spirgatis.)

TURRITE. Syn. with RUTILE.

TUSSILAGO. The root of *Tussilago Petasites*, L. (*Petasites vulgaris*, Desf.) contains, according to Reinsch (N. Jahrb. Pharm. iv. 257), a volatile oil, a crystallisable acid resin, called resinapitic acid, another resin called petasite, the alcoholic solution of which forms, with mineral acids, an emerald-green liquid, afterwards turning blue when hydrochloric acid is used,—besides glucose, mannite, inulin, tannin, and the ordinary plant-constituents.

TURQUOIS. A native hydrated aluminium-phosphate, $2Al^2O^3.P^2O^5.5H^2O$, found in Persia, and much valued as a gem. (See PHOSPHATES, iv. 552.)

TYPE-METAL. Printers' types are made of an alloy of lead and antimony, sometimes with addition of zinc or bismuth, and of tin for stereotype plates (i. 316; iii. 532).

TYPES, CHEMICAL. Bodies analogous in constitution, and exhibiting analogous reactions, are said to belong to the same type. Thus hydrochloric acid, HCl, or rather its multiple nHCl, may be taken as the type of chlorides, which may, in fact, be derived from it by equivalent substitution: *e.g.* KCl, $Ba''Cl^2$, $Sb'''Cl^3$, $Si^{iv}Cl^4$, $As^{v}Cl^5$, &c. In like manner, the sulphates are derived from the type nH^2SO^4, the orthophosphates from the type nH^3PO^4, metaphosphates from $nHPO^3$, &c. In a wider sense, the formula HCl may be taken as the type of chlorides, bromides, iodides, fluorides, and cyanides; H^2O of oxides, sulphides, selenides, tellurides, oxysalts, sulphur-salts, &c.; and H^3N of all amines and amides, and of the corresponding phosphorus, arsenic, and antimony compounds. It is unnecessary to go further into detail on this subject, as it has been fully explained in the article CLASSIFICATION (i. 1007), and, moreover, the system of formulation according to types has been adopted throughout this work. In the present article we shall endeavour to give a sketch of the history of the theories of types and substitution.

GAY-LUSSAC observed that wax, when bleached by chlorine, [illegible] gives up hydrogen, [illegible] of chlorine equal to that of the hydrogen [illegible] removed. Dumas [illegible] with oil of turpentine; and by ext[illegible] ending the investigation to the action of chlorine, bromine, and other elements on various organic substances, he concluded that:—*When a body containing hydrogen is subjected to the dehydrogenising influence of chlorine, bromine, iodine, oxygen, &c., it takes up, for every atom of hydrogen removed, an atom of chlorine, bromine, iodine, or oxygen* [O = 8].

The announcement of this empirical law of substitution gave rise to a large number of experiments in the same direction, especially by Laurent, who first instituted a careful comparison between the properties of the substitution-product and those of the primitive compound, and thence concluded that:—*When equivalent substitution of hydrogen by chlorine or bromine takes place, the chlorine or bromine takes up the position previously occupied by the hydrogen, and plays to a certain extent the same part, so that the chlorinated or brominated product is analogous in constitution to the body from which it has been formed.*

Dumas was at first opposed to this idea, as to the part which the chlorine plays in these substitutions; but afterwards, when a larger number of substitution-products had been obtained (by Laurent, Malaguti, Regnault, and others), and when he himself had discovered trichloracetic acid, and shown it to be analogous in all its reactions to acetic acid, he not only adopted Laurent's views, but even went beyond them, extending them to substitutions by oxygen, and developing them into the theory of types, the main principles of which he laid down, in 1839, as follows:—

1. The elements of a compound may, in numerous cases, be replaced, in equivalent proportions, by other elements, and by compound bodies which play the part of elements.

2. When this substitution takes place in equal numbers of equivalents, the body in which the substitution retains its chemical type, and the elements which have entered into it, play therein the same part as the element which has been abstracted.

The chemical type included bodies containing the same number of atoms of their elements, and resembling one another in their principal chemical properties—such as acetic and trichloracetic acids, or chloroform, bromoform, and iodoform. When, on the other hand, the chemical character of a body was altered by substitution, the number of elementary atoms remaining the same, the two bodies were regarded as belonging to the same mechanical or molecular type: *e.g.* marsh-gas, CH^4; formic acid, CH^2O^2; chloroform, $CHCl^3$; chloride of carbon, CCl^4.

The law of substitution is the expression of facts, which the type-theory was intended to explain. It was not supposed that the type was preserved because substitution took place in equivalent proportions; but the permanence of the type was regarded as a power striving to retain the atoms in the original order, and thus giving to the substitution of one element another. According to this theory, the properties of a compound depend, in many cases, upon the relative positions of its atoms, much more than upon their individual nature.

These views were met with determined opposition by Berzelius and the other upholders of the electrochemical theory. According to that theory, chemical combination consists in the union of atoms or molecules in opposite electrical states, and the function of any element in a compound depends altogether on its electrical polarity. Such a theory is plainly irreconcilable with the idea that a strongly electronegative body like chlorine can take the place of a positive element like hydrogen, and discharge similar functions in the resulting compound. Accordingly, the advocates of the electrochemical theory at first denied the facts upon which the substitution-theory was founded; and afterwards, when these facts had been incontestably established by numerous analyses, sought to explain them in a manner consistent with the principles of the electrochemical theory. With this view, Berzelius endeavoured to show that acetic and trichloracetic acids are differently constituted compounds, acetic acid being an oxide of the radicle C^4H^3, whereas trichloracetic consists of oxalic acid "copulated" with chloride of carbon; thus:

Acetic acid	$C^4H^3.O^3 + HO$
Trichloracetic acid	$C^2Cl^3 + C^2O^3 + HO.$

The numerous substitution-products of acetic ether, formic ether, &c., discovered by Malaguti and Regnault, were likewise formulated by Berzelius in a similar manner: *e.g.*—

Dichlorethylic ether .	$C^4H^3.O^3 + 2C^4H^3.Cl^3$
Perchlorethylic ether .	$C^2O^3 + 5C^2Cl^3$
Dichloracetic ether . .	$2C^4H^3.O^3 + C^4H^3.Cl^3$
Dichloroformic ether .	$2C^2H.O^3 + C^2H.Cl^3 + 2C^4H^3.O^3 + C^4H^3.Cl^3$
Monochloromethyl-oxide .	$C^2H^3.O^3 + C^2H^3.Cl^3$
Dichloromethylic oxide .	$C^2H.O^3 + 2C^2H.Cl^3$
Perchloromethylic oxide .	$CO^2 + 3CCl^2$

TURPETHIC ACID. $C^{34}H^{60}O^{18}$. (Spirgatis, J. pr. Chem. xcii. 97; Jahresb. 1864, p. 591.)—An acid produced by the action of bases on turpethin, $C^{34}H^{56}O^{16}$. When turpethin is dissolved in warm baryta-water, the baryta removed by sulphuric acid, the excess of this acid by lead-hydrate, the latter by sulphydric acid, and the filtrate evaporated, turpethic acid remains as an amorphous yellowish mass, easily soluble in water, having a strong acid reaction, and a bitter somewhat sour taste. It forms two barium-salts, containing $C^{34}H^{58}Ba''O^{18}$ and $C^{34}H^{58}Ba''O^{18}.C^{34}H^{60}O^{18}$. It is resolved by mineral acids into glucose and turpetholic acid.

TURPETHIN. $C^{34}H^{56}O^{16}$. (Spirgatis, *loc. cit.*)—A purgative resin, isomeric with jalapin and scammonin, extracted from the root of *Ipomæa Turpethum* (*vid. sup.*). To prepare it, the root is exhausted with cold water; the dried residue is treated with alcohol, the alcoholic extract concentrated by distillation; the residue mixed with water; and the brown-yellow mass thereby precipitated is repeatedly boiled with water, then dried and shaken up four or five times with ether, and repeatedly precipitated by ether from solution in absolute alcohol.

Turpethin thus prepared is a brownish-yellow inodorous resin, gradually exciting a sharp bitterish taste, and strongly irritating the mucous membranes of the mouth and nose when pulverised. It dissolves easily in alcohol, like jalapin, but is distinguished from that substance by its insolubility in ether. It melts at about 183°, and dissolves slowly in strong sulphuric acid, forming a red liquid. When treated with alkalis, baryta-water for example, it takes up 2 at. water, and is converted into turpethic acid. Under the influence of mineral acids, it is redissolved into glucose and turpetholic acid:

$$C^{34}H^{56}O^{16} + 6H^2O = 3C^6H^{12}O^6 + C^{16}H^{32}O^4.$$

TURPETHOLIC ACID, $C^{16}H^{32}O^4$, separates, in the reaction just described, as a yellowish-white granular conglomerate; and after washing with water, and repeated crystallisation from dilute alcohol, with addition of animal charcoal, forms a white mass, made up of slender microscopic needles. It is inodorous, has an irritating taste and acid reaction, dissolves easily in alcohol, less easily in ether, melts at about 88°, and decomposes at a stronger heat, like jalapinolic acid (iii. 440) giving off a white fume which strongly irritates the eyes and nose.—*Turpetholate of Sodium*, $C^{16}H^{31}NaO^4$, is a white mass, having a silky lustre, and exhibiting, under the microscope, sharply defined rhombic plates, with angles of about 55° and 125°.—The *barium-salt*, $C^{32}H^{62}Ba''O^8$, is amorphous. (Spirgatis.)

TURRITE. Syn. with RUTILE.

TUSSILAGO. The root of *Tussilago Petasites*, L. (*Petasites vulgaris*, Desf.) contains, according to Reinsch (N. Jahrb. Pharm. iv. 257), a volatile oil, a crystallisable acid resin, called resinapitic acid, another resin called petasite, the alcoholic solution of which forms, with mineral acids, an emerald-green liquid, afterwards turning blue when hydrochloric acid is used,—besides glucose, mannite, inulin, tannin, and the ordinary plant-constituents.

TURQUOIS. A native hydrated aluminium-phosphate, $2Al^2O^3.P^2O^5.5H^2O$, found in Persia, and much valued as a gem. (See PHOSPHATES, iv. 552.)

TYPE-METAL. Printers' types are made of an alloy of lead and antimony, sometimes with addition of zinc or bismuth, and of tin for stereotype plates (i. 316; iii. 532).

TYPES, CHEMICAL. Bodies analogous in constitution, and exhibiting analogous reactions, are said to belong to the same type. Thus hydrochloric acid, HCl, or rather its multiple nHCl, may be taken as the type of chlorides, which may, in fact, be derived from it by equivalent substitution: *e.g.* KCl, $Ba''Cl^2$, $Sb'''Cl^3$, $Si^{iv}Cl^4$, $As^{v}Cl^5$, &c. In like manner, the sulphates are derived from the type nH^2SO^4, the orthophosphates from the type nH^3PO^4, metaphosphates from $nHPO^3$, &c. In a wider sense, the formula HCl may be taken as the type of chlorides, bromides, iodides, fluorides, and cyanides; H^2O of oxides, sulphides, selenides, tellurides, oxysalts, sulphur-salts, &c.; and H^3N of all amines and amides, and of the corresponding phosphorus, arsenic, and antimony compounds. It is unnecessary to go further into detail on this subject, as it has been fully explained in the article CLASSIFICATION (i. 1007), and, moreover, the system of formulation according to types has been adopted throughout this work. In the present article we shall endeavour to give a sketch of the history of the theories of types and substitution.

Gay-Lussac observed that wax, when bleached by chlorine, gives up hydrogen, and takes up a volume of chlorine equal to that of the hydrogen removed. Dumas 'ed the same phenomenon with oil of turpentine; and by extending the investigation to the action of chlorine, bromine, and other elements on various organic substances, he concluded that:—*When a body containing hydrogen is subjected to the dehydrogenising influence of chlorine, bromine, iodine, oxygen, &c., it takes up, for every atom of hydrogen removed, an atom of chlorine, bromine, iodine, or oxygen* [O = 8].

The announcement of this empirical law of substitution gave rise to a large number of experiments in the same direction, especially by Laurent, who first instituted a careful comparison between the properties of the substitution-product and those of the primitive compound, and thence concluded that:—*When equivalent substitution of hydrogen by chlorine or bromine takes place, the chlorine or bromine takes up the position previously occupied by the hydrogen, and plays to a certain extent the same part, so that the chlorinated or brominated product is analogous in constitution to the body from which it has been formed.*

Dumas was at first opposed to this idea, as to the part which the chlorine plays in these substitutions; but afterwards, when a larger number of substitution-products had been obtained (by Laurent, Malaguti, Regnault, and others), and when he himself had discovered trichloracetic acid, and shown it to be analogous in all its reactions to acetic acid, he not only adopted Laurent's views, but even went beyond them, extending them to substitutions by oxygen, and developing them into the theory of types, the main principles of which he laid down, in 1839, as follows:—

1. The elements of a compound may, in numerous cases, be replaced, in equivalent proportions, by other elements, and by compound bodies which play the part of elements.

2. When this substitution takes place in equal numbers of equivalents, the body in which the substitution retains its chemical type, and the elements which have entered into it, play therein the same part as the element which has been abstracted.

The chemical type included bodies containing the same number of atoms of their elements, and resembling one another in their principal chemical properties—such as acetic and trichloracetic acids, or chloroform, bromoform, and iodoform. When, on the other hand, the chemical character of a body was altered by substitution, the number of elementary atoms remaining the same, the two bodies were regarded as belonging to the same mechanical or molecular type: *e.g.* marsh-gas, CH^4; formic acid, CH^2O^2; chloroform, $CHCl^3$; chloride of carbon, CCl^4.

The law of substitution is the expression of facts, which the type-theory was intended to explain. It was not supposed that the type was preserved because substitution took place in equivalent proportions; but the permanence of the type was regarded as a power striving to retain the atoms in the original order, and thus giving to the substitution of one element another. According to this theory, the properties of a compound depend, in many cases, upon the relative positions of its atoms, much more than upon their individual nature.

These views were met with determined opposition by Berzelius and the other upholders of the electrochemical theory. According to that theory, chemical combination consists in the union of atoms or molecules in opposite electrical states, and the function of any element in a compound depends altogether on its electrical polarity. Such a theory is plainly irreconcilable with the idea that a strongly electronegative body like chlorine can take the place of a positive element like hydrogen, and discharge similar functions in the resulting compound. Accordingly, the advocates of the electrochemical theory at first denied the facts upon which the substitution-theory was founded; and afterwards, when these facts had been incontestably established by numerous analyses, sought to explain them in a manner consistent with the principles of the electrochemical theory. With this view, Berzelius endeavoured to show that acetic and trichloracetic acids are differently constituted compounds, acetic acid being an oxide of the radicle C^4H^3, whereas trichloracetic consists of oxalic acid "copulated" with chloride of carbon; thus:

Acetic acid	$C^4H^3.O^3 + HO$
Trichloracetic acid	$C^2Cl^3 + C^2O^3 + HO.$

The numerous substitution-products of acetic ether, formic ether, &c., discovered by Malaguti and Regnault, were likewise formulated by Berzelius in a similar manner: *e.g.*—

Dichlorethylic ether .	$C^4H^3.O^3 + 2C^4H^3.Cl^3$
Perchlorethylic ether .	$C^2O^3 + 5C^2Cl^3$
Dichloracetic ether . .	$2C^4H^3.O^3 + C^4H^3.Cl^3$
Dichloroformic ether .	$2C^2H.O^3 + C^2H.Cl^3 + 2C^4H^3.O^3 + C^4H^3.Cl^3$
Monochloromethyl-oxide .	$C^2H^2.O^2 + C^2H^2.Cl^2$
Dichloromethylic oxide .	$C^2H.O^3 + 2C^2H.Cl^3$
Perchloromethylic oxide .	$CO^2 + 3CCl^2$

But these complicated formulæ, which represented compounds evidently analogous in properties, as constituted in entirely different ways, met with little acceptance, more especially as, in order to carry out such modes of representation, it was necessary to invent a new radicle for almost every organic compound that was discovered; and finally, when **Melsens** showed that acetic acid can be reproduced from trichloracetic acid by the action of sodium-amalgam, the idea that these two bodies were differently constituted became altogether untenable. Accordingly, it was then assumed that, as trichloracetic acid was oxalic acid copulated with C^2Cl^3, so acetic acid itself was oxalic acid copulated with C^2H^3:

Acetic acid	. .	$C^2H^3 + C^2O^6 + HO$
Trichloracetic acid	.	$C^2Cl^3 + C^2O^6 + HO$;

and this view was supposed to be supported by the fact that chlorine took the place of hydrogen in the "copula." Similar formulæ were given for methyldithionic acid and the allied compounds discovered by Kolbe:

Trichloromethyldithionic acid	.	$C^2Cl^3 + S^2O^5 + HO$
Dichloromethyldithionic acid	.	$C^2HCl^2 + S^2O^5 + HO$;

and by this fanciful hypothesis of copulæ, the fact of substitution was supposed to be reconciled with the old theory. It is clear, however, that by this mode of explanation, the possibility of chlorine taking the place of hydrogen in a compound, and discharging similar functions therein, was substantially admitted; and thus the main point of the substitution-theory was established.

In this contest between the old radicle-theory and the substitution-theory, the adherents of the latter had somewhat overlooked the good points of the former, resorting almost exclusively to empirical formulæ to represent the relations of compounds. As, however, it was found that mere empirical formulæ did not always represent these relations so clearly as the hypothetical formulæ of the radicle-theory, endeavours were made to construct formulæ which should attain this end without requiring the use of the numerous hypotheses of the radicle-theory. This object was greatly promoted by certain considerations which **Gerhardt** put forward in 1839, and afterwards further developed under the name of "Theory of Residues." He says: "When a so-called replacement of an element by a compound body takes place, the process *is* not a direct substitution; but an element of the one body (*e.g.* H) unites with an element of the other (O), the resulting product (HO) separating out, while the remaining elements (residues) of the two bodies enter into combination." These residues are evidently identical, in many cases, with the radicles of the older theory, and exhibit the relations of compounds to one another with the same clearness, without the necessity of assuming the pre-existence of these radicles in the compounds. In short, the use of them in equations of decomposition shows that a group of elements, or in other words a radicle, may be substituted for an element in a compound, without altering the type.

This process of amalgamation of the radicle and type theories received a great stimulus, in the years 1849 and 1850, by the discovery of the alcoholic ammonia-bases by **Wurtz** and **Hofmann**, which showed that the hydrogen in ammonia, NH^3, may be replaced, partly or even wholly, by an equivalent quantity of the radicles ethyl, methyl, &c., forming bodies of the same nature as ammonia itself. These discoveries, which demonstrated, more clearly than any that had gone before, that organic bodies may be referred to simple inorganic compounds as types, may indeed be regarded as the foundation-stone of the modern type-theory.

Another very important step in the same direction was **Williamson's** discovery of the mixed ethers (1850), and his explanation of the general relations of the ethers and alcohols, by referring them to the type of water, H^2O (Chem. Soc. Qu. J. iv. 106, 229). **Williamson** subsequently extended these views to acids, representing acetic acid, for example, as $\left.\begin{matrix}C^2H^3O\\H\end{matrix}\right\}O$; he also pointed out the possibility of replacing the second atom of hydrogen in the water-molecule by an acid radicle, thereby forming a compound related to acetic acid in the same manner as ether to alcohol (Chem. Soc. Qu. J. iv. 350).—This prediction was verified, in 1852, by Gerhardt's discovery of the anhydrides of acetic acid, benzoic acid, &c. From that time chemists vied with one another, in referring organic bodies to the simplest types of inorganic chemistry; and thus arose the views which were systematised by **Gerhardt** in the fourth volume of his *Traité de Chimie organique*, iv. 560—806. (See also Graham's *Elements of* [illegible]*istry*, 2nd edition, ii. 519—569, and the article CLASSIFICATION in this [illegible] 1015.)

It is usual at the present day to admit four principal types:

HH $\quad OH^2$ $\quad NH^3$ $\quad CH^4$;

or, more generally (denoting monatomic and polyatomic radicles by Roman numerals)

$I + I$ $\quad II + 2I$ $\quad III + 3I$ $\quad IV + 4I$;

and to these, together with the multiple and mixed types, formed by combining two or more of them together, nearly all well-defined compounds may be referred. Sometimes, however it is convenient to refer compounds to types containing radicles of higher atomicity; for example:

Type.	Phosphoric penta-chloride.	Phosphoric oxychloride.	Phosphoric acid.	Stibmethyl-oxide.	Tetrethyl-ammonium-chloride.
$V + 5I$	$P^{v}Cl^5$	$P^{v}\left\{\begin{matrix}Cl^3\\O''\end{matrix}\right.$	$P^{v}\left\{\begin{matrix}(HO)^3\\O''\end{matrix}\right.$	$Sb^{v}\left\{\begin{matrix}(C^2H^5)^3\\O''\end{matrix}\right.$	$N^{v}\left\{\begin{matrix}(C^2H^5)^4\\Cl\end{matrix}\right.$

Type.	Tungstic chloride.	Tungstic oxide.	Sulphuric oxide.	Sulphuric acid.	Sulphuric dibromo-ethylenic diethide.
$VI + 6I$	$W^{vi}Cl^6$	$W^{vi}O^3$	$S^{vi}O^3$	$S^{vi}\left\{\begin{matrix}(HO)^2\\O^2\end{matrix}\right.$	$S^{vi}\left\{\begin{matrix}(C^2H^4)''\\(C^2H^5)^2\\Br^2\end{matrix}\right.$

The union of two or more molecules of the same or different types, by the substitution of a polyatomic element or radicle for an equivalent number of hydrogen-atoms, gives a considerable extension to the power of typical representation; for example:

Type.	Phosphorous chloride.	Phosphoric oxychloride.	Trichlorhydrin.	Citric chloride.
$3HH$	PCl^3	$(PO)'''Cl^3$	$(C^3H^5)'''Cl^3$	$(C^6H^5O^4)'''Cl^3$

Type.	Sulphuric acid.	Succinic acid.	Oxalic acid.	Glycol.
$2H^2O$	$\left.\begin{matrix}(SO^2)''\\H^2\end{matrix}\right\}O^2$	$\left.\begin{matrix}(C^4H^4O^2)''\\H^2\end{matrix}\right\}O^2$	$\left.\begin{matrix}(C^2O^2)''\\H^2\end{matrix}\right\}O^2$	$\left.\begin{matrix}(C^2H^4)''\\H^2\end{matrix}\right\}O^2$

Type.	Phosphoric acid.	Citric acid.	Glycerin.
$3H^2O$	$\left.\begin{matrix}(PO)'''\\H^3\end{matrix}\right\}O^3$	$\left.\begin{matrix}(C^6H^5O^4)'''\\H^3\end{matrix}\right\}O^3$	$\left.\begin{matrix}(C^3H^5)'''\\H^3\end{matrix}\right\}O^3$

Type.	Oxamide.	Succinamide.	Ethylene-diamine.
$2H^3N$	$\left.\begin{matrix}(C^2O^2)''\\H^2\end{matrix}\right\}N^2$	$\left.\begin{matrix}(C^4H^4O^2)''\\H^2\end{matrix}\right\}N^2$	$\left.\begin{matrix}(C^2H^4)''\\H^2\end{matrix}\right\}N^2$

Type.	Sulphurous acid.	Sulpho-phenylic acid.	Methylsulphurous acid.
$\begin{matrix}H\\ \left\{\begin{matrix}H\\ \left.\begin{matrix}H\\H\end{matrix}\right\}O\end{matrix}\right.\end{matrix}$	$\begin{matrix}H\\ \left.\begin{matrix}(SO^2)''\\H\end{matrix}\right\}O\end{matrix}$	$\begin{matrix}C^6H^5\\ \left.\begin{matrix}(SO^2)''\\H\end{matrix}\right\}O\end{matrix}$	$\begin{matrix}CH^3\\ \left.\begin{matrix}(SO^2)''\\H\end{matrix}\right\}O\end{matrix}$

Type.	Hyposulphurous acid.	Type.	Sulphuric chlorhydrate.
$\left\{\begin{matrix}\left.\begin{matrix}H\\H\end{matrix}\right\}O\\ \left.\begin{matrix}H\\H\end{matrix}\right\}S\end{matrix}\right.$	$\begin{matrix}\left.\begin{matrix}H\\(SO)''\end{matrix}\right\}O\\ \left.\begin{matrix}\\H\end{matrix}\right\}S\end{matrix}$	$\begin{matrix}HCl\\ \left.\begin{matrix}H\\H\end{matrix}\right\}O\end{matrix}$	$\left.\begin{matrix}(SO^2)''\\H\end{matrix}\right\}\begin{matrix}Cl\\O\end{matrix}$

Type.	Sulphamic acid.	Carbamic acid.	Oxamic acid.
$\left.\begin{matrix}H^3N\\H^2O\end{matrix}\right\}$	$\begin{matrix}\left.\begin{matrix}H^2\\(SO^2)''\end{matrix}\right\}N\\ \left.\begin{matrix}H\end{matrix}\right\}O\end{matrix}$	$\begin{matrix}\left.\begin{matrix}H^2\\(CO)''\end{matrix}\right\}N\\ \left.\begin{matrix}H\end{matrix}\right\}O\end{matrix}$	$\begin{matrix}\left.\begin{matrix}H^2\\(C^2O^2)''\end{matrix}\right\}N\\ \left.\begin{matrix}H\end{matrix}\right\}O\end{matrix}$

The same compound may, in many cases, be referred to different types. Thus trichloride of phosphorus, PCl^3, may be derived, either from a triple molecule of hydrochloric acid, 3HCl, by substitution of P''' for H^3; or from ammonia, NH^3, by substitution of P for N, and of Cl^3 for H^3. In the same manner, the typical molecule, NH^3, itself may be regarded as three molecules of hydrogen, 3HH, held together by the substitution of N''' for H^3; and the typical molecule of water, H^2O, may also be regarded as two molecules of hydrogen, H^2H^2, held together by the diatomic element, O.

It appears, then, that the different types may also be reduced to one, namely hydrogen, which may therefore be regarded as the representative of the smallest molecular unity, or as the unit of molecule. In other words, all chemical compounds may be regarded as aggregations of ideal hydrogen-molecules, held together by the introduction of one or more polyatomic elements or radicles.

"The reduction of the typical mode of representation to this last consequence, shows plainly that the entire system is nothing more than a comparison of compounds with regard to their composition, not a true theory which can teach us anything about their actual composition itself. The several types are, therefore, not classes of compounds distinctly separated from one another by difference of constitution, but rather movable groups, in which compounds may be placed together, according to the particular analogies which it is desired to bring to light." (Kekulé.)

TYPHA. Two species of this water-plant have been chemically investigated. The pollen of *T. latifolia* contains, according to Braconnot (Ann. Ch. Phys. [2], xlii. 919), 3·6 per cent. stearin and olein, 18·3 sugar, 2·0 starch, 25·9 pollenin, 2·5 magnesium- and potassium-phosphates, together with small quantities of other potassium-salts, and 0·4 silica.

The rootstock of the same plant contains, in the fresh state, according to Lecocq (J. Chim. méd. xlii. 91), in December, 12·5 pts. starch to 73 pts. water; but in April, only 10·5 pts. starch to the same quantity of water. A decoction of the root is said to be used in Turkey as a remedy for dropsy and for snake-bites. (Landerer.)

100 pts. of the entire plant of *Typha angustifolia* contain, after drying, 9·58 per cent. ash; and the ash contains, in 100 pts., 14·8 K^2O, 21·9 CaO, 1·56 MgO, 0·2 Fe^2O^3, 2·5 SO^3, 0·6 SiO^2, 21·0 CO^2, 3·9 P^2O^5, 16·8 KCl, and 16·9 NaCl. (Schulz-Fleeth, Pogg. Ann. cxv. 157.)

TYRITE. See NIOBATES OF YTTRIUM (iv. 55).

TYROLITE. *Copper-froth. Pharmacosiderite. Cupriferous Calamine. Kupaphrite. Kupferschaum.*—A basic arsenate of copper, $\breve{Cu}^3As^2O^8.2Cu''H^2O^2.7H^2O$, or $5Cu''O.As^2O^5.9H^2O$, found native at Falkenstein in the Tyrol, and in other localities, sometimes in trimetric crystals, with the faces $oP \,.\, \infty\breve{P}\infty \,.\, \infty P$, cleaving perfectly parallel to oP; more frequently reniform, massive; structure radiate, foliaceous; surface drusy. Specific gravity = 3·02 to 3·098. Hardness = 1—2. Lustre, pearly on the face oP, vitreous on the other faces. Colour apple-green and verdigris-green, inclining to skyblue. Streak a little paler. Translucent to subtranslucent. Fracture not observable. Very sextile. Thin laminæ flexible. Decrepitates strongly when heated; melts before the blowpipe to a noncrystalline bead, colouring the flame green. On charcoal it emits moisture quietly, and on long exposure to the blowpipe-flame swells a little from escape of arsenic-vapour. With soda it forms an imperfectly fluid mass, containing a white metallic nucleus. Dissolves in acids, with evolution of carbonic acid.

Kobell's analysis (Pogg. Ann. xviii. 253) gave 25·01 per cent. As^2O^5, 43·88 CuO, 17·46 water, and 13·65 carbonate of calcium; or, abstracting the latter, 28·96 per cent. As^2O^5, 50·82 CuO, and 20·22 water, the formula $5Cu^2O.As^2O^5 + 9H^2O$ requiring 29·20 Cu^2O, 50·28 As^2O^5, and 20·52 water.

Copper-froth occurs in the cavities of calamine, calcspar, or quartz, together with other ores of copper, in small aggregated and diverging fibrous groups, having a pale-green colour and delicate silky lustre. (Dana, ii. 426; Rammelsberg, p. 378.)

TYROSINE. $C^9H^{11}NO^3$. (Liebig, [1846], Ann. Ch. Pharm. lvii. 127; lxii. 269.—Warren De la Rue, *ibid.* lxiv. 35.—Bopp, *ibid.* lxix. 20.—Hinterberger, *ibid.* lxii. 72.—Strecker, *ibid.* lxxiii. 70.—Piria, *ibid.* lxxxii. 251.—Alex. Müller, J. pr. Chem. lvii. 162.—Leyer and Köller, Ann. Ch. Pharm. lxxxiii. 332.—Wittstein, Jahresb. 1854, p. 656.—Frerichs and Städeler, *ibid.* 1855, p. 729; 1856, p. 702.—R. Hoffmann, Ann. Ch. [2], iii. 436; Bull. Soc. Chim. 1867, ii. 368.)

A crystalline nitrogenous body, produced by the decomposition of albuminoïdal substances under the influence of acids, alkalis, and putrefaction. It was discovered by Liebig, who obtained it by decomposing casein with melting potash. A. Müller found it amongst the products of the putrefaction of yeast. Leyer and Köller obtained it by the action of fused potash on globulin, feathers, hairs, and hedgehog's prickles, or by treating these bodies with sulphuric acid. Hinterberger prepared it by boiling ox-horn with sulphuric acid. Städeler obtained it in like manner from muscle-fibrin, vegetable fibrin, fibroin, and animal mucus. Städeler has further pointed out that the white bodies, resembling poppy-seeds, sometimes observed in badly-preserved alcoholic anatomical preparations, also consist of tyrosine; and that the so-called cystinoïd tubercles, or xanthocystin, found by Chevallier and Lassaigne on a corpse two months old, likewise agreed in character with this substance.

Tyrosine occurs ready-formed, and always accompanied by leucine, in the animal organism: it has been found in the spleen, and the pancreas; in the liver and in the blood of the hepatic veins, in certain states of liver-disease; in the bile of typhous patients; and in the urine, sometimes forming crystalline sediments (Frerichs and Städeler); in the cutaneous scales in pellagra (Schmetzer). It occurs also in cochineal (De la Rue), probably as a product of decomposition, and in most of the lower forms of animal life. According to Wittstein, it is found in American extract of rhatany.

Preparation.—From Casein.—Well-pressed cheese, prepared from milk, either fresh or curdled, and freed as much as possible from adhering butter, is fused with its own weight of potassium-hydrate (or with solution of potash strong enough to crystallise on cooling) until hydrogen, as well as ammonia, is evolved from the melting mass; the mass is dissolved in hot water, and slightly supersaturated with acetic acid; and the filtered liquid is left to cool, whereupon needles of tyrosine separate, which are purified by repeated solution in water containing potassium-carbonate, and precipitation with acetic acid (Liebig). To purify it from leucine, when obtained in this manner, or according to preparation 5 of leucine (iii. 580), it is recrystallised from hot, and then washed with cold water. It still retains some brown-red matter, to remove which the solution in hydrochloric acid is treated with animal charcoal, decomposed with a quantity of potassium-acetate equivalent to the amount of hydrochloric acid, and rapidly filtered, whereupon the filtrate becomes filled with entangled needles. A portion of the tyrosine remains dissolved in the acetic acid, but the rest is thereby freed from ash, which adheres obstinately to the tyrosine crystallised from neutral solutions. The needles are washed with cold water, and once more crystallised. (Bopp.)

From Horn.—Dilute sulphuric acid (1 pt. oil of vitriol to 4 pts. water) is boiled in a copper vessel with horn-shavings (equal to half the weight of the oil of vitriol) for about twelve hours, renewing the water as it evaporates. The liquid is then diluted with water, mixed with milk of lime to alkaline reaction, and strained; the residue is exhausted with hot water; the liquid evaporated at the boiling heat to about two-thirds the volume of the dilute sulphuric acid, and then neutralised with sulphuric acid; the impure tyrosine, which separates in twenty-four hours, is collected; and an additional quantity is obtained by evaporating the mother-liquor, together with leucine, which must be separated by solution in cold water. The impure tyrosine is next heated with dilute soda-ley; and the tyrosine which separates after twelve hours is again collected, and further purified by recrystallisation from aqueous ammonia. Horn-shavings treated in this manner yield, on the average, 4 per cent. tyrosine and 8 per cent. leucine; fibroïn (silk) and animal mucus more than 4 per cent. tyrosine (Städeler). For Erlenmeyer and Schöffer's determinations of the quantities of tyrosine and leucine obtained by boiling various animal substances with dilute sulphuric acid, see LEUCINE (iii. 579).

Tyrosine, even after repeated crystallisation from aqueous ammonia, is often contaminated with a small quantity of a sulphurous compound, which adheres obstinately to it. To remove this impurity, Städeler dissolves the tyrosine in water, mixes the warm solution with a small quantity of basic lead-acetate, and removes the lead from the clear filtrate by sulphuretted hydrogen. The concentrated solution then yields, by evaporation, perfectly pure tyrosine.

From Cochineal.—Decoction of cochineal is precipitated by neutral acetate or basic nitrate of lead; the liquid is filtered from the carminate of lead, and treated with sulphuretted hydrogen; and the filtrate is evaporated to a syrup, whereupon a chalk-like substance separates. This is washed with cold water, and several times recrystallised from boiling water, ultimately with the aid of animal charcoal. The separated crystals, which have a silky lustre, shrink on the filter to a paper-like mass also having a silky lustre. 300 parts of cochineal yield 1 pt. of tyrosine. (De la Rue.)

Properties.—Tyrosine crystallises from aqueous solution in stellate groups of long slender needles, having a silky lustre, and becoming interlaced and confused in drying. From ammoniacal solutions, it crystallises in permanent tufts of larger needles, also having a silky lustre; and by supersaturating warm dilute hydrochloric acid with tyrosine, a crop of crystals is obtained, consisting of rather thick oblong prisms, with a horizontal dome resting on the narrow sides.

Tyrosine dissolves in 150 pts. of boiling *water*, in 1900 pts. of cold water (at about 16°), in about 13,500 pts. of cold 90 per cent. *alcohol*, not much more freely in boiling alcohol, and is quite insoluble in *ether*. Its solubility in alcohol is greatly increased by admixture with amorphous extractive matter.

Tyrosine-solutions are not precipitated either by *neutral* or by *basic acetate of lead*; but on addition of ammonia, the basic acetate produces a precipitate consisting of tyrosine combined with lead. A solution of tyrosine is not altered by addition of *mercuric acetate*, unless previously mixed with basic acetate of lead; in which case the tyrosine is almost completely precipitated as a mercury-compound, from which it may be separated by sulphuretted hydrogen. An aqueous solution of tyrosine mixed with *mercuric nitrate* remains clear; but on adding a small quantity of soda, a white precipitate is formed, containing tyrosine, mercuric oxide, and nitric acid. A moderately dilute solution of tyrosine boiled with mercuric nitrate, turns red and deposits a brown-red precipitate. Very dilute solutions assume a faint rose-colour, and yield a yellow or flesh-coloured precipitate (R. Hoffmann; Städeler). A small quantity of tyrosine gently warmed with a few drops of strong *sulphuric acid* yields, after dilution with water and neutralisation with barium-carbonate, a liquid which is coloured violet by *ferric chloride*; this reaction affords a very delicate test for tyrosine. (Piria; Städeler.)

Tyrosine heated for some time with *chlorine*, or *bromine*, is converted into perchloroquinone, or perbromoquinone; at ordinary temperatures, on the other hand, bromine forms dibromotyrosine. When chlorate of potassium is added to the hydrochloric acid solution of tyrosine, a wine-red coloration is produced; oily drops separate; and the liquid when distilled yields chlorinated acetone, leaving a resinous mass, which, by the further action of hydrochloric acid and potassium-chlorate, is converted into perchloroquinone.

Tyrosine heated with dilute sulphuric acid and *peroxide of lead* is completely decomposed, carbonic anhydride being slowly evolved, and the brown liquid, when freed from sulphuric acid by means of barium-carbonate, yielding, on addition of alcohol, a dark-coloured precipitate, while the filtrate on slow evaporation deposits a few small crystals.—Alkaline tyrosine-compounds decompose *permanganate of potassium* even in the cold, forming oxalic acid and a brown substance (Neubauer). Tyrosine distilled with *potassium-chromate* and sulphuric acid, yields bitter-almond-oil, hydrocyanic acid, benzoic acid, formic acid, acetic acid, and carbonic acid. (Fröhde.)

Tyrosine heated with *nitric acid*, yields nitro-substitution-products.

Tyrosine is decomposed by *heat*, emitting an odour of burnt horn; when heated in considerable quantity (mixed with pumice-stone), it yields an oily distillate, smelling strongly of phenol (Städeler). But when very small quantities of it are heated in thin glass tubes to about 270°, a white alkaline sublimate, $C^8H^{11}NO$, is obtained, very slightly soluble in water, and forming a crystallisable hydrochlorate and chloroplatinate. This body has the composition of ethyl-oxyphenylamine, $C^6H^6(C^2H^5)NO$, and accordingly tyrosine, from which it is formed by elimination of carbonic anhydride, may be regarded as ethyl-amidosalicylic acid:

$$\underset{\text{Amidosalicylic acid.}}{C^7H^7NO^3} = \underset{\text{Oxyphenylamine.}}{C^6H^7NO} + CO^2.$$

$$\underset{\text{Ethyl-amidosalicylic acid.}}{C^7H^6(C^2H^5)NO^3} = \underset{\text{Ethyl-oxyphenylamine.}}{C^6H^6(C^2H^5)NO} + CO^2.$$

(Schmitt and Nasse, Ann. Ch. Pharm. cxxxiii. 211.) On the other hand, according to L. Barth (*ibid.* cxxxvii. 110), tyrosine, fused with caustic potash, is resolved into paraoxybenzoic acid, acetic acid, and ammonia, as shown by the equation:

$$\underset{\text{Tyrosine.}}{C^9H^{11}NO^3} + H^2O + O = \underset{\text{Paraoxy benzoic acid.}}{C^7H^6O^3} + \underset{\text{Acetic acid.}}{C^2H^4O^2} + NH^3;$$

and may, accordingly, be regarded as the ethylic derivative of amidoparaoxybenzoic acid:

$$\underset{\text{Amidoparaoxybenzoic acid.}}{C^7H^5(NH^2)O^3} \qquad \underset{\text{Tyrosine.}}{C^7H^5(NH.C^2H^5)O^3}.$$

Compounds of Tyrosine.—Tyrosine dissolves in *acids* and in *alkalis*, forming definite compounds. It unites with acids in two proportions, but is not capable of neutralising them. It has rather the properties of a weak acid, decomposing the carbonates of the alkaline earth-metals at the boiling heat, and forming, partly amorphous, partly crystalline compounds, which have a somewhat strong alkaline reaction.

Tyrosine dissolves abundantly in *ammonia*, but crystallises out from the solution unaltered. With the fixed bases, on the contrary, it easily forms definite compounds.

The *barium-compound*, $C^9H^9Ba''NO^3.2H^2O$, forms somewhat sparingly soluble prismatic crystals, more soluble in cold than in hot water. The aqueous solution has an alkaline reaction, and is precipitated by alcohol.—There appears to be also a compound containing $C^9H^9Ba''NO^3.C^9H^{11}NO^3$.—The *calcium-salt*, $C^9H^9Ca''NO^3$, prepared by dissolving tyrosine in lime-water, does not crystallise. A solution of tyrosine boiled with calcium-carbonate, appears to yield a mixture of this salt with the compound $C^9H^9Ca''NO^3.C^9H^{11}NO^3$.—The *sodium-salt*, $C^9H^9Na^2NO^3$, is formed by saturating dilute soda-ley with tyrosine. The solution is alkaline, and is not precipitated by alcohol.

Silver-salts.—On adding a saturated ammoniacal solution of tyrosine, by drops and with constant stirring, to a concentrated solution of silver-nitrate, in such quantity that the liquid no longer smells of ammonia, a heavy amorphous precipitate is formed, containing $C^9H^9Ag^2NO^3.H^2O$. After a certain quantity of the ammoniacal solution has been added, no further precipitation takes place; but if the liquid be then neutralised with nitric acid, the compound $2C^9H^{10}AgNO^3.H^2O$, separates as a heavy crystalline powder. Both compounds are slightly soluble in water, but turn red litmus-paper blue. They dissolve easily in nitric acid and in ammonia, and are decomposed by boiling with water.

Hydrochlorate of Tyrosine, $C^9H^{11}NO^3.HCl$, separates in needle-shaped crystals, on adding an excess of strong hydrochloric acid to a solution of tyrosine in the same acid. Water and dilute alcohol decompose it immediately into tyrosine and hydrochloric acid; but absolute alcohol dissolves it without decomposition, forming a solution which is not precipitated by platinic chloride; the salt is insoluble in ether.

Nitrate.—Tyrosine, triturated to a paste with water, remains colourless when nitric acid is added to it, not in excess; and the liquid filtered from undissolved tyrosine, yields, by spontaneous evaporation, radiate groups of needles, probably consisting of the salt $C^9H^{11}NO^3.HNO^3$.

The *sulphate*, $C^9H^{11}NO^3.H^2SO^4$, is obtained, by treating tyrosine in excess with dilute sulphuric acid, and leaving the filtrate to evaporate, in long slender needles, which are not coloured by ferric chloride, suffer no loss of weight at 115°, and dissolve easily in water; the aqueous solution, however, soon deposits tyrosine.

No compounds of tyrosine with organic acids have yet been obtained.

Derivatives of Tyrosine.

Amidotyrosine, $C^9H^{12}N^2O^3 = C^9H^{10}(NH^2)NO^3$. (G. Beyer, Bull. Soc. Chim. 1867, ii. 369.)—Obtained by reducing nitrotyrosine with tin in presence of dilute hydrochloric acid. The solution, freed from tin by sulphuretted hydrogen, and quickly evaporated (any brown colour that may appear being removed from time to time by sulphuretted hydrogen), yields nearly colourless hydrochlorate of amidotyrosine. To obtain the base, the aqueous solution of this salt is mixed with soda, not in excess, and evaporated to 100°, till it concretes into a thick magma, a resinous matter which forms during the evaporation being previously removed by filtration. The crystalline magma is then left to cool in a vacuum, and freed by pressure from chloride of sodium, which remains in solution.

Amidotyrosine thus prepared is an anhydrous crystalline powder, very soluble in water, slightly soluble in alcohol, permanent in the air when dry, but easily absorbing moisture, and then turning brown. Heated above 100°, it decomposes, and yields by distillation an oleaginous liquid, which solidifies to a crystalline mass on cooling.

Amidotyrosine forms well-crystallised salts.—The *hydrochlorate*, $C^9H^{12}N^2O^3.2HCl.H^2O$, crystallises in long needles, and sometimes forms a white hygroscopic powder. It gives off its water at 120°, without coloration. The aqueous solution quickly acquires a violet-brown colour. It is more soluble in alcohol than the free base. The solution at the boiling heat quickly reduces silver-oxide and platinic chloride to the metallic state, a resin soluble in ammonia being formed at the same time.—The *acid sulphate*, $C^9H^{12}N^2O^3.2H^2SO^4$, separates on cooling in anhydrous nodules, soluble in water, when the hydrochlorate is evaporated over the water-bath with dilute sulphuric acid.—The *neutral sulphate*, $C^9H^{12}N^2O^3.H^2SO^4$, is formed on adding the free base to an equivalent quantity of the acid salt in concentrated solution, and separates in well-defined crystals; it reduces oxide of silver.—*Sulphate of zinc and amidotyrosine*, $ZnSO^4.2(C^9H^{12}N^2O^3.H^2SO^4)$, is obtained in the crystalline state from a mixture of the two sulphates.

Dibromotyrosine, $C^9H^9Br^2NO^3.2H^2O$. (Gorup-Besanez.)—The hydrobromate of this base, produced by the action of bromine-vapour on excess of tyrosine, splits up, when boiled with water, into hydrobromic acid and dibromotyrosine. The base separates from concentrated solutions, in slender white needles; from more dilute solutions, after some time, in fan-shaped groups of large rhomboïdal tables, or in thick prismatic crystals belonging to the triclinic system. The crystals are, at first, perfectly transparent, but, when exposed to the air, gradually give off their water of crystallisation, and become milkwhite. Dibromotyrosine is more soluble in hot than in cold water, sparingly soluble in alcohol, insoluble in ether; has a slightly bitter taste, an acid reaction, and gives off the whole of its crystallisation-water at 100°. At a higher temperature it decomposes, giving off an odour like that of phenyl-compounds. It dissolves in alkalis, with decomposition, and formation of metallic bromide; and when treated with nitric acid, immediately becomes reddish, gives off bromine, and forms a solution, which, on evaporation, gradually deposits crystals of dinitrotyrosine.

Dibromotyrosine unites with acids and with bases, forming compounds which may be prepared similarly to those of tyrcsine itself.—The *silver-compound*, $C^9H^7Br^2Ag^2NO^3$, is a white crystalline precipitate, which turns brown on exposure to light, is decomposed by boiling with water, also by nitric acid, which separates bromide of silver.

Hydrobromate of Dibromotyrosine, $C^9H^9Br^2NO^3.HBr$, crystallises in stellate groups of small nacreous needles, easily soluble in water and in alcohol, but decomposed by boiling with water.—The *hydrochlorate*, $C^9H^9Br^2NO^3.HCl\,.\,\frac{3}{2}H^2O$, gives off its water of crystallisation at 100°, and in other respects resembles the hydrobromate.—The *sulphate*, $(C^9H^9Br^2NO^3)^2.H^2SO^4$, forms interlaced needles, easily soluble in water and in alcohol.

Nitrotyrosine, $C^9H^{10}(NO^2)NO^3$. (Strecker, Ann. Ch. Pharm. lxxiii. 70.)—When tyrosine is suspended in four times its bulk of water, and a quantity of nitric acid of specific gravity 1·3, equal in volume to the water, is gradually added, the solution becomes warm, acquires a red colour, and, after standing for twelve hours in a warm place, deposits an abundant crystallisation of nitrate of nitrotyrosine; and on pressing these crystals between paper, dissolving them in water, and adding as much ammonia as can be added without reddening, nitrotyrosine is deposited: it may also be separated from the solutions of its salts by acetate of ammonium.

Nitrotyrosine forms delicate yellow needles, united in warty groups, or in beautiful wavellitic crystalline geodes. It is slightly soluble in cold, more soluble in hot water, insoluble in alcohol and ether, has a slightly bitter taste, reddens litmus, and decomposes with slight detonation when heated above 100°. It dissolves in ammonia, the fixed alkalis, and dilute mineral acids, but not in acetic acid.

Nitrotyrosine unites with acids and with bases, in the same manner as tyrosine.—The *barium-salt*, $Ba''[C^9H^9(NO^2)NO^3]^2$, is a blood-red amorphous mass.—The *silver-salt*, $C^9H^8Ag^2(NO^2)NO^3$, is an orange-yellow precipitate, soon changing to a deep red granular powder, somewhat soluble in water; there appears also to be another silver-compound containing $C^9H^9Ag(NO^2)NO^3$.

Hydrochlorate of Nitrotyrosine, $2[C^9H^{10}(NO^2)NO^3.HCl].H^2O$, crystallises in tufts of lemon-yellow needles, easily soluble in water and in alcohol.—The *nitrate*, $C^9H^{10}(NO^2)NO^3.HNO^3$, forms lemon-yellow needles, insoluble in ether, easily soluble in alcohol, soluble in 5 pts. of water; the solution decomposes on standing, depositing nitrotyrosine.—*Sulphate of Nitrotyrosine*, $2C^9H^{10}(NO^2)NO^3.H^2SO^4$, forms yellow needles or granules.

Dinitrotyrosine, $C^9H^9(NO^2)^2NO^3$. (Städeler, Jahresb. 1860, p. 576.)—Produced by gently heating nitrate of nitrotyrosine with a mixture of equal volumes of water and nitric acid of specific gravity 1·3. On washing the lemon-yellow residue with cold water, and recrystallising it from boiling water, the dinitrotyrosine is obtained in golden-yellow shining laminæ. It is very slightly soluble in cold water, not much more in hot water, easily soluble in alcohol, less soluble in ether; has a slight acid taste; makes a deep yellow stain; melts at 115°, and decomposes with slight detonation.

Dinitrotyrosine unites easily with metals, forming red and yellow salts, which detonate violently when heated.—The *ammonium-salt* crystallises from an aqueous solution mixed with alcohol and ether, in stellate groups of needles, having a deep chrome-red colour with violet reflex.—The *barium-salt*, $C^9H^7Ba''(NO^2)^2NO^3.2H^2O$, crystallises in rather thick ruby-coloured prisms, more soluble than the calcium-salt.—The *calcium-salt*, $C^9H^7Ca''(NO^2)^2.NO^3.3H^2O$, is precipitated in golden-yellow six-sided tables, on adding ammonia to a solution of dinitrotyrosine mixed with chloride of calcium: it is insoluble in alcohol and ether, slightly soluble in water, more readily in dilute acetic acid.—The *lead-salt* separates, on mixing a solution of dinitrotyrosine with acetate of lead, in orange-coloured flocks, which, if left in the liquid, gradually become crystalline, and are converted into large stars, formed of chrome-red hexagonal tables.—The *magnesium-salt* crystallises in stellate tufts of very delicate bright-red needles.—The *silver-salt* is precipitated by ammonia, from a solution of dinitrotyrosine mixed with silver-nitrate, in red flocks, which soon become crystalline.

Erythrosin.—This name is given by Städeler to the red colouring-matter, formed when tyrosine is dissolved in excess of nitric acid, or when a solution of tyrosine-nitrate is left to evaporate in the air, and probably also by the action of ozone on tyrosine (Gorup-Besanez). It is a red-brown substance, insoluble in the ordinary solvents, but easily soluble in alcohol containing sulphuric acid, from which solution it is partly precipitated by ammonia, the remaining liquid being green by transmitted, red and opaque by reflected light. Erythrosin dissolves in the fixed alkalis with brown-red or violet colour, in strong sulphuric acid also with violet colour. Städeler thinks it not improbable that this body may be identical with hæmatoïdin.

TYROSINE-SULPHURIC ACID. (Frerichs and Städeler, Jahresb. 1854, p. 675.—Städeler, Ann. Ch. Pharm. cxvi. 57; Jahresb. 1860, p. 577.)—Tyrosine forms, with sulphuric acid, several acids containing the radicle SO^2.—α. On heating it to 100°, with four or five times its weight of strong sulphuric acid, a monobasic acid, $C^9H^{11}NO^3.SO^3$, is formed, which, on diluting with water, neutralising with carbonate of barium, and decomposing the filtrate with sulphuric acid, is partly precipitated, together with the barium-sulphate, as anhydrous crystalline acid, and partly separates, on evaporating the mother-liquor, as hydrated pulverulent acid, $C^9H^{11}NO^3.SO^3.2H^2O$.

The crystalline acid is very slightly soluble in cold water, dissolves slowly in hot water, and is gradually deposited from this solution, on evaporation, or on addition of hydrochloric or nitric acid, in prisms or tables; it is but very slightly soluble in alcohol, even at the boiling heat.—The hydrated acid is a starchlike powder, containing from 0·8 to 12 per cent. water, and much more soluble in water and alcohol than the crystalline acids (12 per cent. water = 2 at.).

Tyrosine-sulphuric acid has a strong acid reaction, and produces, with a small quantity of ferric chloride, a splendid violet colour—or rose-red in very dilute solutions. Its salts, which are mostly very soluble, and likewise produce the violet colour with ferric chloride, are amorphous, and not precipitable by nitrate of silver or neutral acetate of lead, but yield a precipitate with the basic acetate.—The *ammonium-salt*, $C^9H^{10}(NH^4)NO^3.SO^3.H^2O$, gives off water and ammonia when heated, and then becomes acid.—The *barium-salt*, $C^9H^{10}Ba''NO^3.SO^3.2H^2O$, and the *calcium-salt*, $C^9H^{10}Ca''NO^3.SO^3.2\frac{1}{2}H^2O$, have an alkaline reaction, and disagreeable saline bitter taste.

β. When tyrosine and sulphuric acid are heated in the proportions above mentioned, but more strongly and for a longer time, an acid is formed, the barium-salt of which has the same composition as the above, but a neutral reaction and sweet taste.

γ. By strongly heating tyrosine with 8 to 12 pts. sulphuric acid, dibasic acids are produced, the barium-salts of which still yield the violet colour with ferric chloride, but differ in composition and in their other properties from those above described. One of these barium-salts, crystallised in nodules, was tasteless, had an alkaline reaction, dissolved slightly in cold, more freely in hot water, and was found to consist of $C^9H^9Ba''NO^3.SO^3.3H^2O$.

δ. The action of sulphuric acid on tyrosine at high temperatures appears also to yield other acids, resulting from more advanced decomposition: they all give the violet colour with ferric chloride, but have not been further examined. (Städeler.)

U

UIGITE. A mineral from Uig, in the Isle of Skye, containing 52·40 per cent. silica, 17·98 alumina, 9·97 lime, 0·36 magnesia, 0·03 potash, 1·40 soda, and 17·83 water. It has a white to light-yellow colour, nacreous lustre, hardness = 5·5, and specific gravity = 2·284. Before the blowpipe it melts quietly and easily to an opaque enamel. (Heddle, N. Jahrb. f. Mineral. 1858, p. 823.)

ULEXITE. Syn. with BOROCALCITE (i. 643).

ULLICO. Attempts have been made in Holland to cultivate the root of *Ullico tuberosus* on the large scale as a substitute for the potato. 100 pts. of the fresh root contain 87·9 pts. water, 10·95 organic matter, and 1·15 ash. 100 pts. of the dry substance contain 3·1 pts. fat (mostly crystallisable), 29·4 fruit-sugar (with extractive matter and a little resin), 4·0 gum, 33·3 starch, 11·9 solid albumin, 18·3 cellulose, and other insoluble substances. The dry root contains 2·6 per cent. nitrogen, equivalent to 17 per cent. albuminous substance. The ash contains lime, ferric oxide, soda, sulphuric acid, phosphoric acid in large quantity, chlorine, and carbonic acids, together with small quantities of magnesia, potash, and silica. (**Mulder** and **Schablée**, Pharm. Centr. 1851, p. 269.)

ULLMANITE. Antimonial or antimonio-arsenical nickel-glance, $NiS.Ni(Sb;As)^2$ (iv. 43).

ULMARIC ACID. Buchner's name for spiræic or salicylous acid, obtained from *Spiræa ulmaria.*

ULMIC ACID. ULMIN. See the next article.

ULMOUS or **HUMOUS SUBSTANCES.** These names are given to various brown or black substances, occurring in vegetable mould, peat, stable-manure, dung-water, and certain mineral waters, and resulting from the putrefaction of vegetable or animal substances in contact with air and water. Similar substances are produced by the action of acids and alkalis on cellulose, starch, sugar, fibrin, albumin, &c.; but the composition of these products appears to vary according to the circumstances under which they are formed, and the nature of the reagents used in preparing them.

When sugar is boiled for some time with dilute hydrochloric, nitric, or sulphuric acid, black or brown scales are deposited, which, after being washed with water, dissolve partially in ammonia, leaving a black insoluble substance called ulmin; and the ammoniacal solution, when neutralised with an acid, deposits brown or black gelatinous flocks of ulmic acid, soluble in pure water, but insoluble in water containing free acid or sulphate of potassium. Ulmic acid and ulmin have the same composition, $C^{24}H^{18}O^9$, according to Stein (Ann. Ch. Pharm. xxx. 84), differing from that of sugar only by the elements of water. Ulmic acid is converted into ulmin by prolonged desiccation, and more quickly by boiling with strong hydrochloric acid.

When vegetable mould, or mouldered wood from the trunk of a decaying tree, is digested in a weak solution of potash or soda, a brown liquid is formed, which, on addition of an acid, yields a blackish-brown precipitate, easily soluble in alkalis, and always retaining a considerable proportion of nitrogen. Mulder (Ann. Ch. Pharm. xxxvi. 243) regards this precipitate as a mixture of three substances, which are compounds of water, or of water and ammonia, with three different acids, viz.—geic acid, $C^{20}H^{12}O^7$; humic acid, $C^{20}H^{12}O^6$; and ulmic acid, $C^{20}H^{14}O^6$. These formulæ are very doubtful, but the substances in question are obviously the product of vegetable matter in a state of decay more or less advanced. They are very much like the above-mentioned products of the decomposition of sugar.

The name "ulmic acid," or "ulmin," was given by Klaproth to a gummy substance contained in the black alkaline excrescences on the stems of unhealthy trees, especially of elms.

Ulmin is also the name of a brown pigment, produced by the action of strong acids or alkalis on various organic bodies, especially by heating treacle or alcohol with strong sulphuric acid, thoroughly washing the residue with water, then triturating it with gum, and drying the mixture. A similar colour is obtained by boiling alcohol with solid caustic potash, washing the product with hydrochloric acid, and then with water.

For details respecting the various observations which have been made upon ulmous or humous substances, see *Gmelin's Handbook*, xvii. 458.

ULMUS. The bark of the common elm, *Ulmus campestris*, contains tannin, resin, mucus, and inorganic salts; the mucus, according to Braconnot, is very much like that of linseed. The bark of old elms often exudes gummy or mouldy substances, containing vegetable mucus, together with the carbonates of potassium, calcium, and magnesium. Klaproth's ulmin was a substance of this kind. The leaves of the elm are said to contain a bitter principle and a yellow colouring-matter, and (according to Kellerman) the flowers, at the time when the buds turn red, contain a red and a green colouring-matter.

The composition of the ash of the bark and wood is as follows:—

	K^2O.	Na^2O.	CaO.	MgO.	$Fe'''PO^4$.	P^2O^5.	SO^3.	SiO^2.	
Bark	2·2	10·1	72·7	3·2	1·2	1·2	0·6	8·8	= 100
Wood	21·9	13·7	47·8	7·7	1·7	2·8	1·3	3·1	= 100

ULTENITE. A rock occurring in the Ulten Valley in the Tyrol, consisting of a crystalline, fine-grained, slaty mixture of garnet with disthene and a small quantity of mica.

ULTRAMARINE. *Outremer.*—The fine blue pigment known by this name consists essentially of silica, alumina, soda, and sulphur, and is regarded as a sodio-aluminic silicate, united either with polysulphide of sodium alone, or with a polysulphide and a polythionate of sodium.

Ultramarine occurs native in several minerals, to which it imparts its blue colour, and the characteristic property of giving off sulphydric acid and yielding a jelly of silica, when treated with hydrochloric acid; such are nosean, hauyne, ittnerite, and especially lapis-lazuli, which occurs intergrown with limestone, and mixed with iron-pyrites, in Siberia, Thibet, China, and on the Cordillera of Ovalle in South America. From this mineral, ultramarine was formerly obtained by gently calcining the stone, broken into fragments of about the size of hazelnuts; quenching the heated fragments in vinegar, by which they were rendered more friable and were deprived of adhering carbonate of calcium;—then pulverising them; levigating the powder for a long time with a thin syrup of honey and dragon's-blood; mixing it to a paste with a resinous cement composed of colophony, white pitch, yellow wax, and linseed-oil; then leaving it at rest for some days; and extracting the ultramarine from it by suspension in water, and decantation. By this protracted mechanical treatment, the ultramarine was obtained in the form of a very fine soft powder, of various shades of blue, the portions first deposited being the darkest, and the last constituting a pale-blue powder called ultramarine ash (*cendres d'outremer*).

This process being very tedious, and the lapis-lazuli being a rare mineral, obtainable only from remote and difficultly accessible localities, natural ultramarine was necessarily a very costly article; and of late years, it has been entirely superseded by artificial ultramarine, which can be made equal, or even superior, to the natural product in colour and lustre, and at a price low enough to admit of its extensive use as a pigment.

The idea of preparing ultramarine artificially was suggested by the discovery of blue masses, more or less resembling it, on taking down soda-furnaces and limekilns. Tessaert, in 1814, found a blue mass of this kind in a soda-furnace at St. Gobain, and gave it to Vauquelin for analysis, who pronounced it to be lapis-lazuli (Ann. Chim. lxxxix. 88). Kuhlmann found on the hearth of a salt-cake furnace, similar blue masses surrounded with very small brown-red crystals of sodium-sulphide (Dumas' *Traité de Chimie appliquée*, ii. 419.) A similar observation was made by Hermann in Schönebeck. These observations induced the *Société d'Encouragement* at Paris, in 1824, to offer a prize of 6,000 francs for the discovery of a mode of preparing ultramarine artificially; and this prize was awarded to Guimet, of Toulouse, in 1828. A mode of obtaining artificial ultramarine had, however, been previously discovered by Christian Gmelin, and published by him at the beginning of the year 1828 (Würtemberg Naturw. Abhandl. ii. 191). Guimet's process was first applied on the manufacturing scale, but it was kept secret. Gmelin's process is as follows:—

Soda-ley saturated with precipitated silica, is mixed with aluminium-hydrate (containing 20 per cent. water, and obtained by precipitation from alum not containing iron), in such proportion that the mixture shall contain 31 pts. dry silica to 26 pts. dry alumina; the liquid is then evaporated to dryness, and the pulverised residue is mixed with flowers of sulphur. In the next place, the same quantity of a mixture of dry sodium-sulphate and flowers of sulphur, in equal parts, is weighed out; the whole carefully mixed and stamped into a crucible, so as to fill it completely; the crucible, tightly closed, is quickly heated to redness, so that the sulphur may not volatilise before the sulphide of sodium can be formed; and the mass is kept at a red heat for two hours. The crucible is then left to cool with the cover on, and the greenish-yellow product (*green ultramarine*) is gently heated in porous crucibles, in which narrow channels have been bored to increase the draught. The blue mass thus obtained is finely pulverised, levigated, and washed.

Gmelin's process includes all the conditions essential to the preparation of a good ultramarine; all the more recent processes, indeed, differ from it, chiefly, in using clay instead of the artificially prepared mixture of silica and alumina. At the present day, manufacturers of ultramarine use mixtures of kaolin with Glauber-salt and charcoal, or with carbonate of soda and sulphur, or carbonate of soda and Glauber-salt together. The mixture is ignited in closed crucibles or boxes of fireclay; and the green ultramarine thus obtained is ground in a mill, and then roasted, with addition of sulphur, to convert it into blue ultramarine. Gentele (Dingl. pol. J. cxli. 116; cxlii. 350) gives the three following mixtures:

Kaolin, anhydrous	100	100	100
Calcined Glauber-salt	83 to 100	. .	41
Carbonate of soda	. .	100	41
Charcoal	17	12	17
Sulphur	. .	60	13

The colouring-matter of ultramarine has been made the subject of investigation by many chemists, but considerable doubt still exists as to its true nature. According to the experiments of Wilkens (Ann. Ch. Pharm. xcix. 21), who has made careful analyses of a variety of samples of artificial ultramarine, both from his own manufactory and from other sources, ultramarine is composed of two portions, one of which—regarded by him as the essential constituent—is constant in composition, and is attacked with facility by hydrochloric acid, evolving sulphuretted hydrogen; while the other portion, not soluble in hydrochloric acid, contains a variable amount of sand, clay, oxide of iron, and sulphuric acid. Wilkens's analyses of the pure blue pigment correspond nearly with the formula $(2Al^2O^3.3SiO^2).(Al^2O^3.4SiO^2).Na^2S^2O^3.3Na^2S$.

	Calculation.	Analyses.		
Silica	37·6	40·25	39·39	46·19
Aluminium . . .	27·4	26·62	26·40	25·85
Sulphur	14·2	13·42	12·69	13·27
Soda (Na^2O) . . .	20·0	19·89	21·52	20·69

Numerous other analyses are given in the *Handwörterbuch der Chemie* (ix. 19).

Wilkens regards the blue colouring-principle as a compound of hyposulphite and sulphide of sodium. He states that the presence of iron is not essential to the production of the colour, but about this there is still some doubt. According to Brunner, a corresponding compound, in which potassium-sulphide is substituted for sodium-sulphide, is colourless.

Ultramarine heated in the air, gradually assumes a dull green hue; it is not changed by heating with sulphur, but when melted with borax, gives off sulphur and sulphurous acid, and leaves a colourless glass. Sulphuric, nitric, and hydrochloric acids decompose it, quickly destroying the colour. Chlorine acts still more rapidly, dissolving everything but the silica, and completely discharging the colour.

Ultramarine is extensively used, not only as an artist's colour, but also for paper-staining and other forms of house-decoration, as well as in dyeing and calico-printing. In Germany, which is the chief seat of the ultramarine manufacture, there are about twenty factories, each producing annually about 1000 tons of the colour. The manufacture is also carried on in France and in Belgium, and to a smaller extent in England.

ULVA. The alga called *Ulva* or *Rivularea gelatinosa*, consists, according to Braconnot, of green globules and a colourless jelly; the latter is insoluble in water, at first, but dissolves on prolonged immersion. The solution resembles gum-water, but when treated with nitric acid, yields oxalic instead of mucic acid.

UMBELLIC ACID. This name was given by Persoz to a product of the oxidation of the volatile oil of anise, star-anise, and fennel with chromic acid. Hempel has, however, shown that the acid thus obtained is identical with anisic acid.

UMBELLIFERONE. $C^6H^4O^2$. (Sommer and Zwenger, Ann. Ch. Pharm. cxv. 15.—Mössmer, *ibid.* cxix. 260.)—A neutral body, isomeric or polymeric with quinone, to which, however, it exhibits no further resemblance. It is obtained by the dry distillation of various resins, chiefly of those derived from umbelliferous plants: thus crude galbanum yields, by dry distillation, 0·83 per cent. umbelliferone; sagapenum, 0·32 per cent.; *Asa fœtida*, 0·28 per cent. It is likewise obtained from opoponax, the resins of sumbul-root, angelica-root, *Radix levistici*, *R. meu*, and *R. imperatoriæ*. Gum-ammoniac does not yield it, but it may be obtained from the alcoholic extract of the bark of the mezereon or spurge-laurel (*Daphne mezereum*), a plant not belonging to the umbelliferous order.

Umbelliferone may be prepared from galbanum;—most advantageously, according to Mössmer, from the resin purified by boiling crude galbanum with water, dissolving the resinous residue in milk of lime, and precipitating the filtered solution with hydrochloric acid. By distilling this purified resin with water, an oily distillate is obtained, which, on standing, deposits crystals of umbelliferone, to be purified by recrystallisation. The distillate obtained from the alcoholic extract of mezereon-bark, contains daphnetin as well as umbelliferone. To separate the former, the solution of the purified crystals is mixed with acetate of lead, which throws down a compound of daphnetin with lead-oxide, while pure umbelliferone remains in solution, and crystallises on evaporation. Umbelliferone is likewise formed when a concentrated alcoholic solution of pure galbanum-resin, saturated with hydrochloric acid gas, is heated for some time to 100°.

Umbelliferone forms colourless rhombic prisms, having a faint silky lustre; it is tasteless, inodorous in the cold, dissolves slightly in cold water, and so abundantly in boiling water, that a solution, saturated while hot, coagulates, on cooling, to a crystalline pulp, forming, when dry, a coherent interlaced mass. Umbelliferone dissolves also in alcohol, ether, and chloroform. The aqueous solution is colourless by transmitted light, but exhibits, by reflected light, a splendid blue colour, which is deepened by addition of alkalis, but weakened or destroyed by acids.

Umbelliferone, when warmed (also its aqueous solution when boiled), emits an odour like that of coumarin. It melts, at 240°, to a yellowish liquid, which solidifies in the crystalline form on cooling; it sublimes below its melting-point, and volatilises without residue.

Umbelliferone does not appear to unite either with acids or with bases, and is not precipitated from its solutions by any salt except basic acetate of lead; the white precipitate thereby produced is decomposed by washing. Umbelliferone dissolves in most acids with aid of heat, not being decomposed even by strong sulphuric acid. Nitric acid converts it into oxalic acid. It reduces gold- and silver-salts, but does not appear to reduce an alkaline cupric solution.

Dibrom-umbelliferone, $C^6H^2Br^2O^2$, is produced by treating an alcoholic solution of umbelliferone with bromine, and separates in flocks, which may be purified by washing with water, then with dilute alcohol, and recrystallisation from alcohol. It is white and insoluble in water; its alcoholic solution exhibits a superficial light-green iridescence. (Mössmer.)

Dry umbelliferone is scarcely attacked by *chlorine*; but the aqueous solution, when treated with chlorine, is quickly decomposed, depositing a small quantity of a chocolate-coloured powder.

UMBER. *Umbra. Terre fine de Turquie umber. Argile ochreuse brune.*—A pigment, consisting of an argillaceous brown hæmatite, essentially $2Fe^2O^3.SiO^2.H^2O$, with alumina and manganic oxide, according to the analyses of Klaproth and v. Merz. It was originally obtained from Umbra, in the Papal States, but is now imported chiefly from Cyprus. It forms chestnut-brown to liver-brown amorphous masses, having a hardness of 1·5 to 2·5, and a specific gravity of 2·2. It feels meagre, adheres to the lips, and gives the reaction of iron. It dissolves partially in cold hydrochloric acid, and to a greater extent in hot hydrochloric acid, with evolution of chlorine. When heated it gives off water, turns dark-brown, and then constitutes the pigment called raw umber; by stronger heating, it is completely dehydrated, becoming red-brown and softer, and then constitutes burnt umber. It is used both as an oil- and water-colour, frequently mixed with other colours.

Cologne umber, Cologne-earth, or Cologne-brown is an earthy lignite, sometimes used as a pigment instead of real umber.

UNGHWARITE. A hydrated iron-silicate, allied to nontronite, occurring in Hungary, at Haar near Passau in Bavaria, and on the Meenser Steinberg, near Göttingen, in amorphous, yellowish-green to pistachio-green, opaque masses, imbedded in or mixed with opal. Its composition has not been exactly determined, inasmuch as the quantitative relations of the silica and water are rendered very variable by the admixture of opal. Von Hauer (Wien. Akad. Ber. xii. 161) obtained, as a mean of ten analyses, 57·76 per cent. silica, 20·86 ferrous oxide, 1·77 lime, and 19·78 water. Chloropal (i. 921) is merely opal coloured with unghwarite.

UNIO. The blood of *Unio pictorum* is a mobile, alkaline, slightly bluish liquid, which, after separation from the body of the mussel, deposits yellow fibrinous flocks, while the remaining liquid becomes turbid on boiling, but not when mixed with acetic or nitric acid. (Witting, J. pr. Chem. lxxiii. 121.)

UNIONITE. This name appears to have been given to two distinct minerals, viz. oligoclase and zoisite, both occurring at Unionville in Pennsylvania.

UNITARY THEORY. *Système unitaire.*—This term was applied by Gerhardt to the system of Chemistry in which the molecules of all bodies are compared, as to their magnitude, with one unit molecule—water, for example,—and all chemical reactions are, as far as possible, reduced to one typical form of reaction, namely double decomposition. This system has been fully illustrated throughout the present work, and therefore need not here be considered in further detail. (See Atomic Weights, i. 457—473; Chemical Affinity, i. 855—858; Classification, i. 1015—1022; Formulæ, ii. 695; Gases, Combination of, by Volume, ii. 809; Molecule, iii. 1027; Types, v. 926; also Gerhardt, *Introduction à l'étude de la Chimie par le système unitaire*, 1848; and further *Traité de Chimie organique*, iv. 563, *et seq.*)

UPAS is the Malay term for arrow-poison, especially for that obtained from plants (for which also, in Celebes and Borneo, the name *ipo* is used). Generally speaking, however, the term "upas" is applied to two particular arrow-poisons used in the East Indies—namely, *Upas Antjar*, and *Upas Radja*, or *Upas Tieutè*.

Upas Antjar is prepared from the milky juice of *Antiaris toxicaria*, the poison-tree of Macassar. The juice, dried at 100°, contains from 3·5 to 3·7 per cent. antiarin (i. 310), a compound which kills rabbits inoculated with $\frac{1}{30}$ grain of it, or even less. For the preparation of the arrow-poison, the juice is mixed with ground pepper, onion-juice, zerumbet, parts of a species of arum called *njampoo*, dragon's-blood, and other substances. The mixture is not boiled, but slowly inspissated to a red-brown resinous mass, which is left to dry in the sun. It resembles opium when dry, and forms a brown emulsion with water. According to Mulder, it contains, besides antiarin, a non-poisonous resin, gum, sugar, and inorganic salts. When injected into the circulation, ¼ grain of it is fatal to rabbits, ½ grain to dogs, and from 4 to 6 grains to larger animals, such as buffaloes. It likewise kills when taken into the stomach, but in that case larger doses appear to be required.

Upas Radja, or Upas Tieuté, also called Upas Tjettik, and in the remoter parts of India, Sung-sig (dagger-poison), is prepared from the younger roots, and the bark of the older roots of *Strychnos Tieuté*, a shrub growing in the forests of Java, by boiling for an hour with addition of various less essential ingredients. It is brownish-black when fresh, resembles opium when dry, has a bitter taste, is for the most part soluble in alcohol, and, according to Pelletier and Caventou, contains as its active constituents, strychnine and brucine. According to Horsfield and Mayer, it acts in the same manner as the fresh extract of *Strychnos Tieuté*. It is regarded in India as the strongest and most dangerous of arrow-poisons.

The bulbs of certain amaryllidaceous plants, *Crinum asiaticum* and *Cr. moluccanum*, which exert an emetic and diaphoretic action, are used in the East as remedies in cases of wounding by poisoned arrows.

URACONISE. Syn. with URANIUM-BLOOM.

URALITE. A pseudomorph of hornblende, after augite, from the Ural.

URALITE-PORPHYRY. An aphanite-porphyry occurring in the Ural, containing uralite, and sometimes also crystals of labradorite.

URALORTHITE. Orthite from the neighbourhood of Lake Ilmen, near Miask, in the Ural, formerly mistaken for tscheffkinite.

URAMIL. Syn. with DIALURAMIDE (ii. 315).

URAMILIC ACID. *Dialuramic Acid* (Laurent). (Liebig and Wöhler, Ann. Ch. Pharm. xxvi. 314.—Gregory, Phil. Mag. xxiv. 187.)—Obtained by boiling a solution of dialuramide in cold sulphuric acid with water, or by evaporating a solution of thionurate of ammonium with a moderate quantity of sulphuric acid. It forms transparent four-sided prisms; or, by rapid crystallisation, silky needles; they redden litmus slightly, and turn red at about 100°, without losing weight. It dissolves in 6 or 8 pts. cold and 3 pts. hot water, and in sulphuric acid without blackening or evolution of gas. It forms crystallisable salts with the alkalis, and precipitates barium-, calcium-, and silver-salts on addition of ammonia; the silver-precipitate contains about 64 per cent. silver (Liebig and Wöhler). It dissolves quietly in cold nitric acid, but is decomposed by boiling with strong nitric acid. When it is boiled with dilute hydrochloric or sulphuric acid, dialuric acid is formed, which is partially converted into alloxantin by the action of the air. (Gregory.)

The formula assigned by Liebig and Wöhler to uramilic acid is $C^8H^{10}N^5O^{7\frac{1}{2}}$, the percentage they obtained by analysis is C, 32·09; H, 3·59; N, 23·23; O, 41·09; but they do not state at what temperature their crystals were dried. Gmelin suggests $C^8H^9N^5O^7$, which is the formula adopted by Laurent (Compt. rend. xxxv. 629), who regards the compound as dialuramic acid, $N.C^8H^6N^4O^6.H^2.H.O$. Gerhardt (*Chim. org.* i. 510), relying on Gregory's experiments, regards it as acid dialurate of ammonium, the formula of which is $C^8H^{11}N^5O^8 = C^8H^7(NH^4)N^4O^8$. F. T. C.

URANATES. Compounds of the uranic oxide with basic metallic oxides.

URANIC ACID. A name applied to uranic oxide when in combination with bases.

URANIN. Syn. with pitchblende or native oxide of uranium

URANITE. Native calcio-uranic phosphate (iv. 585).—*Chalcolite*, or *copper-uranite*, is an isomorphous mineral having the calcium replaced by copper.

URANIUM. *Atomic weight*, 120; *Symbol*, U.—Klaproth, in 1789, discovered, in pitchblende and uranite, a metallic oxide to the metal of which he gave the name uranium. Its compounds were subsequently examined by Richter, Buchholz, Lecanu, Brande, and especially by Berzelius and Arfvedson.* Péligot, in 1840, showed that the body previously regarded as metallic uranium was really the protoxide (UO); he likewise obtained the true metal, and determined its atomic weight correctly. Further examinations of uranium-compounds have been made by Ebelmen, Rammelsberg, Wertheim, Patera (J. pr. Chem. lxi. 397), Drenkmann (Jahresb. 1861, p. 255), and others.

---

* For references, see *Gmelin's Handbook*, iv. 157.

Uranium is not a very abundant metal. Its principal ore is pitchblende, which consists of impure uranoso-uranic oxide; it occurs also as carbonate in liebigite (i. 798); as sulphate in johannite, or uranium-vitriol, and in uranium-ochre (p. 616); as phosphate in uranite or uranium-mica (iv. 584); as niobate and tantalate in uranotantalite or samarskite; in smaller quantity also in tyrite, bragite, fergusonite (iv. 55), pyrochlore, and polycrase (iv. 57), and as niobate and titanate in euxenite (ii. 611).

Extraction.—Uranium is almost always obtained from pitchblende, a mineral containing from 40 to 90 per cent. of uranoso-uranic oxide, U^3O^4, associated with sulphur, arsenic, lead, iron, and several other metals. The mineral is finely pounded, freed by elutriation from the finer earthy impurities; roasted for a short time to remove part of the sulphur and arsenic; then dissolved in nitric acid, and the solution evaporated to dryness. The residue is exhausted with water; the solution filtered from the brick-red residue of ferric oxide, ferric arsenate, and lead-sulphate; the greenish-yellow filtrate is slightly concentrated by evaporation, and left to cool, whereupon it deposits crystals; and the resulting radiated mass of crystallised uranic nitrate is drained on a funnel, and then washed with a small quantity of cold water. As the water dissolves a portion of the crystals, it is used in a subsequent operation to redissolve the residue obtained by evaporating the solution of pitchblende in nitric acid. The uranic nitrate, after being dried in the air, is introduced into a wide-mouthed bottle containing ether, in which it immediately dissolves; the yellow solution is left to evaporate in the air; and the resulting crystals are purified by solution in hot water and recrystallisation. The mixed mother-liquids, after dilution with water, are treated with sulphydric acid to precipitate arsenic, lead, and copper, and the filtrate is freed from oxide of iron by evaporating to dryness, and digesting the residue in water. The solution thus obtained yields a fresh crop of crystals of uranic nitrate. This salt is converted by ignition into uranoso-uranic oxide, U^3O^4, and from this the protoxide is obtained by ignition with reducing agents, and the protochloride by ignition with charcoal in a stream of chlorine-gas. (Péligot, Ann. Ch. Phys. [3], v. 5; xii. 258.)

Ebelmen digests pulverised pitchblende with hydrochloric acid, to dissolve the oxides of calcium, magnesium, manganese, and other metals; roasts the washed and dried residue with charcoal; exhausts the cooled mass with strong hydrochloric acid, to remove iron, copper, and lead as completely as possible; again roasts the washed residue, and then dissolves it in hydrochloric acid. The solution thus obtained is evaporated to dryness and again treated with water, which leaves arsenate of iron undissolved; the filtrate is treated with sulphydric acid, and evaporated to the crystallising point; and the resulting crystals of uranic nitrate are purified by recrystallisation.

Metallic uranium is obtained by decomposing the protochloride with potassium or sodium. If the mixture be heated in a platinum-crucible over a spirit-lamp, and the soluble alkaline chloride washed out by water, the uranium is obtained in the form of a black powder, or sometimes aggregated on the sides of a crucible in small plates, having a silvery lustre and a certain degree of malleability. But, by introducing into a porcelain-crucible, first a layer of sodium, then chloride of potassium, and then a mixture of chloride of potassium and protochloride of uranium (the use of the chloride of potassium being to moderate the action, which is otherwise very violent), placing the porcelain-crucible within a closed earthen crucible lined with charcoal, and heating it, first moderately, till the reduction takes place, and then strongly in a blast-furnace for fifteen or twenty minutes, the metal is obtained in fused globules. (Péligot.)

Uranium, in its compact state, is somewhat malleable and hard, but is scratched by steel. Its specific gravity is 18·4; its colour is like that of nickel or iron. When exposed to the air, it soon tarnishes, and assumes a yellowish colour. At a red heat it oxidises with vivid incandescence, and becomes covered with a bulky layer of black oxide, which protects the interior from oxidation. In the pulverulent state it takes fire at about 207°, burning with great splendour, and forming a dark-green oxide, U^3O^4. It is permanent in the air at ordinary temperatures, and does not decompose cold water. It dissolves with evolution of hydrogen in dilute acids, forming green solutions. It combines directly with chlorine, giving out great light and heat, and forming a green volatile chloride. It unites directly with sulphur at a slightly elevated temperature. (Péligot.)

Uranium forms two classes of compounds—viz., the uranous compounds, in which it is biequivalent, *e.g.* $U''O$, $U''Cl^2$, $U''SO^4$, &c.; and the **uranic compounds**, in which it is triequivalent; *e.g.*:

$\overset{\prime\prime\prime}{U}{}^2O^3$	$\overset{\prime\prime\prime}{U}{}^2\left\{\begin{matrix}O^2\\Cl^2\end{matrix}\right.$	$\overset{\prime\prime\prime}{U}{}^2\left\{\begin{matrix}O^2\\(NO^3)^2\end{matrix}\right.$	$\overset{\prime\prime\prime}{U}{}^2\left\{\begin{matrix}O^2\\(SO^4)''\end{matrix}\right.$
Oxide.	**Oxychloride.**	**Oxynitrate.**	**Oxysulphate.**

There are also two oxides of uranium, intermediate between uranous and uranic oxide. There is no chloride, bromide, iodide, or fluoride corresponding to uranic oxide, such as UCl^3; neither are there any normal uranic oxysalts analogous to the normal ferric salts, such as $\overset{\prime\prime\prime}{U}(NO^3)^3$, $\overset{\prime\prime\prime}{U}{}^2(SO^4)^3$, &c.; but all the uranic salts contain the group U^2O^2, which may be regarded as a diatomic radicle (called **uranyl** by Péligot), uniting with acid radicles in the usual proportions, and forming normal salts, thus:—

Uranic oxide, or Oxide of Uranyl	$(U^2O^2)''O$
Uranic oxychloride, or Chloride of Uranyl . . .	$(U^2O^2)''Cl^2$
Uranic nitrate, or Nitrate of Uranyl	$(U^2O^2)''(NO^3)^2$
Uranic sulphate, or Sulphate of Uranyl	$(U^2O^2)''SO^4$.

This view of the composition of the uranic compounds is, however, by no means essential, since they may also be formulated as above.

URANIUM, BROMIDES OF. *a. Uranous Bromide*, UBr^2, is obtained, in the anhydrous state, by heating a previously ignited and still warm mixture of 1 pt. uranous oxide and 6 pts. starch in a stream of bromine-vapour. It is a brown pulverulent mass, exhibiting a crystalline structure on the most strongly heated portions; it fumes in the air, and is very deliquescent. (Hermann, Jahresb. 1861, p. 260.)

By dissolving uranous hydrate in aqueous hydrobromic acid, a dark-green liquid is formed, which, when evaporated over oil of vitriol, yields dark-green crystals of hydrated uranous bromide, $UBr^2.4H^2O$; they are very deliquescent, yield an emerald-green solution, and are decomposed by heat, giving off bromine and leaving uranous oxide.

Uranic Oxybromide, $U^2O^2Br^2$, or *Bromide of Uranyl*, $(U^2O^2)''Br^2$, is produced by treating uranous oxide with bromine and water, or by dissolving uranic oxide in hydrobromic acid, and evaporating. It forms yellow needles, which have a styptic taste, give off water and become orange-yellow when heated; and at a stronger heat, in contact with the air, give off hydrobromic acid and bromine, and leave uranic oxide. They deliquesce in the air, and their solution gives, with ammonia, a precipitate of uranic hydrate. (Berthemot, Ann. Ch. Phys. [3], xliv. 387.)

URANIUM, CHLORIDES OF. Uranium forms a dichloride and an oxychloride, analogous to the bromine-compounds just described, also a subchloride analogous to the suboxide.

The *Subchloride*, U^4Cl^6, obtained by strongly igniting the dichloride in hydrogen-gas, forms a coarsely fibrous, dark-brown, slightly volatile mass. It dissolves easily in water, but the purple solution is quickly converted into uranous chloride, with evolution of hydrogen and deposition of a red powder. Ammonia throws down the hydrated suboxide.—According to Rammelsberg, a brown subchloride, U^3Cl^4, is formed by heating the dichloride in ammonia-gas.

The *Dichloride*, or *Uranous chloride*, UCl^2, is formed, with vivid incandescence, by burning metallic uranium in chlorine-gas; also by igniting uranous oxide in hydrochloric acid gas. It is prepared by passing chlorine over an intimate mixture of charcoal and either of the oxides of uranium, strongly heated in a tube of very refractory glass. It crystallises in dark-green regular octahedrons, which have a metallic lustre, and, when heated to redness, volatilise in red vapours, and form a sublimate. It is very deliquescent, fumes strongly on exposure to the air, and dissolves easily in water, with a hissing noise and great rise of temperature, forming a dark emerald-green solution, which, when evaporated in a vacuum, leaves an amorphous, green, deliquescent mass of uranous chloride; but when evaporated by heat, gives off hydrochloric acid, and leaves a residue soluble in water (probably an oxychloride). The solution of uranous chloride, when boiled, gives off hydrochloric acid and deposits a very finely-divided brown powder. When the same solution is dropped into boiling water, the whole of the uranium is precipitated as uranous hydrate. Alkalis also throw down uranous hydrate. The solution of uranous chloride is a powerful deoxidising agent, reducing gold- and silver-salts, completely converting ferric chloride into ferrous chloride, &c.

Dry uranous chloride ignited in hydrogen-gas, gives off a fourth of its chlorine, and is reduced to U^4Cl^6.—Dry ammonia-gas converts it, at ordinary temperatures, into the compound $3UCl^2.2NH^3$; at a red heat, reduction takes place, and the subchloride is produced.

Uranic Oxychloride, or *Chloride of Uranyl*, $U^2O^2Cl^2$.—When dry chlorine-gas is passed over uranous oxide at a red heat, the tube becomes filled with an orange-yellow vapour of this compound, which solidifies in a yellow crystalline mass, easily fusible, but not very volatile. When ignited with potassium, it yields chloride of potassium and uranous oxide. Dissolved in water, it forms hydrated chloride of uranyl, $U^2O^2Cl^2.H^2O$. The same solution of uranic oxychloride is formed when a solution of uranous chloride is exposed to the air, or treated with nitric acid. When evaporated, it yields, according to Klaproth, crystals which effloresce on exposure to the air; according to Arfvedson, an uncrystallisable syrup.

Uranic oxychloride forms double salts with the chlorides of the alkali-metals.—The *ammonium-salt*, $2NH^4Cl.U^2O^2Cl^2.2H^2O$, crystallises, after some time, from a syrupy solution, in very deliquescent rhombohedrons (Péligot).—The *potassium-salt*, $2KCl.U^2O^2Cl^2.2H^2O$, is obtained by dissolving uranate of potassium in excess of hydrochloric acid, adding chloride of potassium, and evaporating. The crystals dissolve readily in water; but on evaporating the resulting solution, chloride of potassium crystallises out, and uranic oxychloride remains in solution.—*Chloride of sodium* appears to form a similar double salt.—Uranic oxychloride also forms double salts with the hydrochlorates of organic bases. (C. Gr. Williams.)

URANIUM, CYANIDES OF. But little is known respecting these compounds. Uranous oxide does not dissolve in hydrocyanic acid, and the precipitate formed by cyanide of potassium in uranous solutions consists merely of hydrated uranoso-uranic oxide. (Rammelsberg.)

With uranic salts, cyanide of potassium forms a yellow precipitate, probably consisting of uranic oxycyanide. This precipitate dissolves when warmed in excess of potassium-cyanide, and is not reprecipitated therefrom by acids, perhaps in consequence of the formation of a uranium-compound analogous to ferricyanide of potassium. (Fresenius and Haidlen.)

URANIUM, DETECTION AND ESTIMATION OF. 1. *Blowpipe Reactions.*—Uranic oxide and salts, fused with *phosphorus-salt* in the outer blowpipe-flame, produce a clear yellow glass, which becomes greenish on cooling. In the inner flame the glass assumes a green colour, becoming still greener when cold. Similar colours are obtained with *borax*. The oxides of uranium are not reduced to the metallic state by fusion with carbonate of soda on charcoal.

2. *Reactions in Solution.*—α. Uranous salts are formed by dissolving uranous oxide in strong hydrochloric or sulphuric acid, or the hydrate in dilute acids, also by reduction of uranic salts. They are green or greenish-white, and yield green aqueous solutions, from which *caustic alkalis* throw down a red-brown gelatinous precipitate of uranous hydrate; *alkaline carbonates* (with evolution of carbonic anhydride), green precipitates, which dissolve in excess of alkaline carbonate, especially of ammonium-carbonate, forming green solutions: the green precipitate, after washing and drying, consists of pure uranous hydrate. Uranous salts also yield a green precipitate with *phosphate of sodium*, grey-green with *oxalic acid*, light-brown with *ferrocyanide of potassium*. *Sulphide of ammonium* forms a black precipitate of uranous sulphide; the acid and neutral solutions are not precipitated by *sulphydric acid*. Uranous salts are easily oxidised to uranic salts by exposure to the air, or by treatment with nitric acid; they easily reduce *gold-* and *silver-salts*.

β. Uranic salts are yellow; they are mostly soluble in water, and in solution have a bitter taste, without any metallic aftertaste. They are reduced to uranous salts by *sulphydric acid*; also by *alcohol* or *ether* in sunshine.—*Caustic alkalis*, added to uranic solutions, throw down a yellow precipitate, consisting of a uranate of the alkali-metal, which is insoluble in excess of the reagent.—*Alkaline carbonates* produce a yellow precipitate, consisting of a carbonate of uranium and the alkali-metal, soluble in excess, especially in acid carbonate of potassium or acid carbonate of ammonium. Potash added to these solutions throws down all the uranic oxide. From the solution in carbonate of ammonium, the uranic oxide is likewise precipitated by boiling.—*Carbonate of barium* completely precipitates uranic oxide from its solutions at ordinary temperatures.—*Phosphate of sodium*, added to uranic salts not containing too much free acid, produces a white precipitate of uranic phosphate, having a slight tinge of yellow.—*Sulphide of ammonium* produces a black precipitate of uranic sulphide, which remains for a long time suspended in the liquid.—*Sulphydric acid* produces no precipitate.—*Ferrocyanide of potassium* produces a dark red-brown precipitate; *ferricyanide of potassium*, none.—Metallic *zinc* does not precipitate uranium in the metallic state from uranic solutions, but, after a long time, produces a yellow precipitate of uranic oxide.

4. *Estimation* and *Separation.*—Uranium is completely precipitated from uranic solutions by *ammonia*. The precipitate, which consists of hydrated uranic oxide containing ammonia, must be washed with water containing sal-ammoniac, as it runs through the filter when washed with pure water. It is then dried and ignited in an open crucible,

whereby it is converted into uranoso-uranic oxide, U^3O^4; but to obtain a perfectly definite result, and prevent further oxidation during cooling, it is necessary to put the cover on the crucible while the substance is still red-hot, and keep it there till the crucible is quite cold. The oxide thus obtained contains 84·90 per cent. of uranium. An accurate result is likewise obtained by igniting the sesquioxide in an atmosphere of hydrogen, whereby it is reduced to protoxide containing 88·24 per cent.of the metal.

If the uranic solution contains a considerable quantity of an earth or a fixed alkali, the precipitate formed by ammonia carries down with it a certain portion of the earth or alkali, to free it from which it must, before ignition, be redissolved in hydrochloric acid, and reprecipitated by ammonia.

From the alkali-metals, uranium, in the state of uranic salt, is separated by *ammonia*, attention being paid to the precaution just mentioned. A method of separating uranic oxide from alkalis, founded on the solubility of uranic silicofluoride in alcohol, is given by Stolba (*Zeitschr.* anal. Chem. iii. 71; Jahresb. 1864, p. 718).

From barium it is separated by *sulphuric acid*; from *strontium* and *calcium*, also by sulphuric acid with addition of alcohol.

From magnesium, manganese, cobalt, nickel, and zinc, these metals being in the state of protoxide, and the uranium in the state of sesquioxide, it is separated by precipitation with *carbonate of barium*.—From zinc, cobalt, and nickel it may also be separated by mixing the solution of the chlorides with excess of sodic acetate, and passing a rapid stream of sulphydric acid into the boiling liquid: the zinc, cobalt, and nickel are then completely precipitated, while the whole of the uranium remains dissolved. (Gibbs, Sill. Am. J. [2], xxxix. 58; Jahresb. 1865, p. 727.)

From iron it is separated by *carbonate of ammonia*, both metals being in the state of sesquioxide; the uranic oxide then dissolves, while the ferric oxide remains undissolved. Care must, however, be taken that the carbonate of ammonia be really monocarbonate, quite free from excess of carbonic acid, otherwise the iron will also be dissolved. To ensure this condition, the carbonate of ammonia must be previously boiled, and the solution of the oxides, if acid, must be neutralised with ammonia till a slight permanent precipitate begins to form: the solution should then be diluted with water. The uranic oxide is separated from the filtrate either by boiling, or by supersaturation with hydrochloric acid and precipitation by ammonia.

From aluminium, uranium is also separated by *carbonate of ammonia*, and with greater facility.

From cadmium, copper, lead, tin, and all other metals whose salts are insoluble in dilute acids (Group i. ANALYSIS, i. 217), uranium is separated by *sulphydric acid*; from *chromium*, in the same manner as iron is seperated from that metal (i. 945); and from vanadium, tungsten, molybdenum, and tellurium, by *sulphide of ammonium*, in which the sulphides of the last-named metals are soluble.

For the methods of separating uranium from niobium, tantalum, and titanium, see those metals (iv. 51; v. 664, 839).

Volumetric Estimation.—Acid manganic phosphate, added to an acid solution of ammonio-uranic acetate, forms a yellowish-white precipitate, which, when the precipitation is quite complete, changes its colour to yellowish rose-red (from formation of basic manganic phosphate). The reaction may be applied to the volumetric estimation of uranium, by dissolving 1 to 1½ grm. of the uranium-compound in dilute nitric or in nitromuriatic acid, supersaturating with ammonium-carbonate, then diluting the solution, and adding excess of acetic acid, till the liquid is made up to a litre. If phosphoric or arsenic acid is present, the uranium must first be precipitated by sulphide of ammonium. The normal solution of manganic phosphate is prepared by strongly heating syrupy phosphoric acid with finely-divided manganic oxide, till a dark-blue colour is produced, diluting to such a degree that 1 grm. of uranium shall correspond to 30 cubic centimetres, and titrating with pure uranous or uranic oxide. (Guyard, Bull. Soc. Chim. 1863, p. 89; Jahresb. 1863, p. 692.)

Belouheber (Bull. Soc. Chim. 1867, i. 494) estimates uranium volumetrically by means of potassic permanganate, the uranium-salt being previously brought to the minimum of oxidation by treatment with zinc and sulphuric acid.

5. *Atomic Weight of Uranium.*—Péligot, in 1842 (Ann. Ch. Pharm. xlii. 141), determined the proportion of chlorine contained in uranous chloride, UCl^2, by precipitation with nitrate of silver. Two experiments gave 39·1 and 37·2 per cent. chlorine, therefore 60·9 and 62·8 per cent. uranium. The latter, regarded by Péligot as the more correct, gives:

$$U = \frac{62{\cdot}8}{37{\cdot}2} \cdot 71 = 119{\cdot}9.$$

The analysis of uranic acetate, $U^2O^2(C^2H^3O^2)^2.H^2O$, made by Péligot, in 1845 (*ibid.* lx. 183) gave U = 120·0 and 120·1. Wertheim (J. pr. Chem. xxix. 209), by analysis of sodio-uranic acetate, and Ebelmen (Ann. Ch. Pharm. xlii. 286), by analysis of uranic oxalate, obtained somewhat lower numbers; but the number 120 is regarded as the true atomic weight of uranium.

URANIUM, FLUORIDES OF. *Uranous fluoride*, UF^2, is produced, together with uranic oxyfluoride, by the action of aqueous hydrofluoric acid on green uranoso-uranic oxide, and separates as a green insoluble powder, which passes through the filter. It is more easily prepared by boiling the yellow solution of uranic oxyfluoride, obtained as above, or a solution of ammoniacal uranic oxide or carbonate in hydrofluoric acid, with stannous chloride; the precipitate of uranous fluoride thus produced is easy to wash. Uranous fluoride is also formed by the action of hydrofluoric acid on uranous hydrate, and is thrown down by hydrofluoric acid from a solution of uranous chloride, as a bulky green precipitate. When heated in hydrogen-gas, it gives off hydrofluoric acid, and leaves a reddish mass, insoluble in water, scarcely attacked by strong nitric acid, and probably consisting of a subfluoride. (Bolton, Zeitschr. f. Chem. [2], ii. 353; Bull. Soc. Chim. 1866, ii. 450.)

Potassio-uranous fluoride, $KF.2UF^2$, is produced by the action of formic or oxalic acid, under the influence of light, on potassio-uranic oxyfluoride (*infra*). When oxalic acid is used, a precipitate of uranous hydrate is likewise formed, but it is easily separated from the double fluoride by solution in dilute acids. Potassio-uranous fluoride is a green powder resembling uranous fluoride, insoluble in water and in dilute acids, soluble in strong hydrochloric acid. Sulphuric acid dissolves it easily, eliminating hydrofluoric acid. When ignited in the air it melts, gives off hydrofluoric acid, and leaves uranate of potassium; ignited in a close vessel, it leaves a black residue of uranium-suboxide and fluoride of potassium. Caustic soda separates the suboxide from it. Heated in hydrogen-gas, it behaves like uranous fluoride. (Bolton.)

Sodio-uranous fluoride, $NaF.2UF^2$ (?), resembles the potassium-salt, but appears to be more soluble in water. When heated it does not melt, but decomposes like the potassium-salt, leaving a yellow residue of sodium-uranate. (Bolton.)

Uranic Oxyfluoride, or *Fluoride of Uranyl*, $U^2O^2F^2$.—The yellow solution, obtained by treating green uranoso-uranic oxide or uranic hydrate with hydrofluoric acid, leaves, on evaporation, a nearly white uncrystallisable mass, which dissolves in water and in alcohol (Berzelius; Bolton). It gives off water at 100°, and, when heated in the air, gives off fluorine and leaves uranium-oxide (Bolton). It forms double salts with alkaline fluorides.

The *ammonium-salt*, $(NH^4)F.U^2O^2F^2.xH^2O$, obtained like the potassium-salt (*infra*), forms indistinct crystals, soluble in water, slightly soluble in hydrofluoric acid, and insoluble in alcohol. When calcined it leaves suboxide of uranium. (Bolton.)

The *barium-salt*, $3BaF^2.2U^2O^2F^2.2H^2O$, is a yellow crystalline precipitate, insoluble in cold water, soluble in dilute acids.

The *potassium-salt*, $3KF.U^2O^2F^2$, separates, on adding fluoride of potassium in excess to uranic nitrate, as a lemon-yellow, dense, crystalline precipitate; it is also formed by dissolving uranate of potassium in hydrofluoric acid mixed with fluoride of potassium. It separates from solution in boiling water in anhydrous crystalline crusts, and is deposited by slow evaporation in macled crystals belonging to the quadratic system: it is anhydrous. When heated, it melts, with partial decomposition, to a red liquid, which solidifies to a yellow mass on cooling. It dissolves without decomposition in boiling water, forming a solution which does not attack glass. Fused with carbonate of sodium, it yields fluoride and uranate of sodium. Ignited in hydrogen, it leaves a residue consisting of uranium-fluoride, uranium-suboxide, and potassium-fluoride. By formic or oxalic acid, under the influence of light, it is reduced to potassio-uranous fluoride (Bolton).—The *sodium-salt*, $NaF.U^2O^2F^2.4H^2O$, is sometimes obtained, in fine efflorescent right rhomboïdal prisms, by evaporating a mixture of sodium-fluoride and uranic nitrate, or a solution of sodium-uranate in hydrofluoric acid; but on attempting to recrystallise it, fluoride of sodium crystallises out alone. By formic or oxalic acid it is reduced to sodio-uranous fluoride. (Bolton.)

URANIUM, IODIDES OF. *Uranous iodide*, UI^2, is obtained by dissolving uranous hydrate in hydriodic acid; the green solution, when evaporated in contact with the air, acquires a brown colour from separation of iodine, and yields a black crystalline mass, insoluble in water, and containing a small quantity of uranic oxyiodide. (Rammelsberg.)

URANIUM, OXIDES OF. Uranium forms four compounds with oxygen—viz., uranous oxide, UO; uranic oxide, U^2O^3; and two intermediate oxides, U^4O^5 and U^3O^4, which may be regarded as compounds of the other two.—A suboxide, U^4O^3, appears also to be precipitated, in combination with water, on adding ammonia to the aqueous solution of the subchloride, U^2Cl^3; but the brown precipitate thus produced, quickly takes up oxygen from the water, and is converted into a greenish-yellow hydrate, which, in contact with the air, oxidises further to uranous hydrate.

Uranous Oxide, UO.—This oxide, formerly mistaken for the metal, is obtained by exposing uranoso-uranic oxide, U^3O^4, mixed with charcoal-powder, bullock's blood, or oil, to the strongest heat of a blast-furnace; by heating the same oxide to redness in a current of dry hydrogen; by igniting uranic oxalate in a close vessel, or (better) in a current of hydrogen; or by igniting potassio-uranic chloride (p. 943), either alone or in hydrogen.

Uranous oxide obtained by the last-mentioned process forms, after washing, a metallically lustrous powder composed of microscopic regular octahedrons, translucent with red-brown colour on the edges (Arfvedson). That which is prepared from the oxalate is a cinnamon-brown or copper-red metallically lustrous powder, of specific gravity 10·15 (Péligot; Ebelmen); that prepared by reducing uranoso-uranic oxide with charcoal is an iron-grey powder, consisting of feebly lustrous microscopic needles (Bucholz). When a solution of ammonium-uranate in hydrochloric acid is evaporated with sal-ammoniac and common salt, the remaining mass heated in a covered crucible till the sal-ammoniac volatilises and the sodium-chloride melts, and the soluble salts washed out with water, uranous oxide remains in the form of a black crystalline powder (Wöhler). The black anhydrous oxide is also formed by boiling uranous hydrate with water.

Uranous oxide easily passes to a higher state of oxidation, the compact crystalline variety, however, less rapidly than the finely-divided oxide; that prepared from the oxalate at not too strong a heat is even pyrophoric. Uranous oxide, when heated, burns with a glimmering light, and is converted into uranoso-uranic oxide.

Uranous hydrate is precipitated from uranous salts by caustic alkalis, in bulky red-brown flocks, which retain a portion of alkali after washing with cold water, and turn black on boiling.

Uranous oxide, after ignition, is insoluble in dilute hydrochloric or sulphuric acid, but dissolves in strong sulphuric acid. The hydrate dissolves easily in acids, forming uranous salts. (For the reactions of those salts, see p. 943).

Uranoso-uranic Oxide, U^3O^4 – $UO.U^2O^3$.—This oxide forms the principal constituent of pitchblende. It is obtained artificially by igniting the metal or uranous oxide in contact with the air; by heating uranous oxide to redness in an atmosphere of aqueous vapour; and by gentle ignition of uranic oxide or uranic nitrate. It is a dark-green velvety powder, of specific gravity 7·1 to 7·3. When ignited alone it is reduced to the black oxide, U^4O^5; by ignition in hydrogen, or with sodium, charcoal, or sulphur, it is reduced to uranous oxide.

Pitchblende sometimes occurs in regular octahedrons, or combinations of the octahedron with the cube and rhombic dodecahedron, but more generally massive and botryoïdal. Hardness = 5·5. Specific gravity = 6·468—8. Lustre submetallic or greasy to dull. Colour greyish, greenish, brownish-red, or velvet-black. Streak brownish-black or olive-green, a little shining. Opaque. Fracture conchoïdal, uneven. It contains from 70 to 90 per cent. uranous oxide, together with sulphur, lead, arsenic, antimony, bismuth, iron, manganese, cobalt, magnesium, calcium, carbonic acid, phosphoric acid, silica, and sometimes traces of fluorine (Rammelsberg's *Mineralchemie*, p. 175). It occurs, accompanying various ores of lead and silver, at Johanngeorgenstadt, Marienberg, and Schneeberg in Saxony, at Joachimsthal and Przibram in Bohemia, and at Retzbanya in Hungary. It is associated with uranite at Tincroft and Tolcarn near Redruth in Cornwall, and at Adrianople in Turkey.

Uranoso-uranic oxide and ground pitchblende are used for producing a very permanent black colour under the glaze of porcelain.

Uranoso-uranic oxide is but little acted upon by dilute hydrochloric or sulphuric acid; but these acids, when concentrated, dissolve it without alteration; by nitric acid it is dissolved, and oxidised to uranic nitrate. A solution of uranoso-uranic acid in hydrochloric or sulphuric acid, diluted with water and mixed with ammonia, yields a grey-green precipitate of uranoso-uranic hydrate, which, if precipitated in the cold, dissolves easily and without alteration in dilute acids, but is decomposed by carbonate of ammonium, which dissolves out uranic oxide, leaving brown uranous hydrate. On mixing the solution of uranoso-uranic oxide in sulphuric acid with alcohol, uranous sulphate separates out, while uranic sulphate remains dissolved. The solution of uranoso-uranic oxide in hydrochloric acid is decomposed in the same manner on addition of sulphuric acid and alcohol. Hence it would appear that the solutions of uranoso-uranic oxide in acids are mixtures of uranous and uranic salts, a view which is likewise in accordance with their other reactions.

A black oxide of uranium, U^4O^5 or $2UO.U^2O^3$, is produced by subjecting uranic nitrate or uranate of ammonium to intense ignition, or by strongly igniting uranous oxide prepared by Wöhler's method in contact with the air. This oxide is regarded by Péligot and Drenkmann as a distinct compound; according to Rammelsberg and Ebelmen, on the other hand, it is only a mixture of green uranoso-uranic oxide with uranic oxide. If not too dense, it is oxidised by prolonged ignition in contact with the air. With acids it behaves in the same manner as the green oxide. The black colour produced upon porcelain in the manner above mentioned, probably consists of this oxide.

Uranic Oxide, or **Oxide of Uranyl,** $U^2O^3 = (U^2O^2)''O$.—Uranium and its lower oxides dissolve in nitric acid, with evolution of nitric oxide, and formation of uranic nitrate; and when this salt is heated in a basin till it begins to decompose, and then to 250° in a glass tube, as long as acid fumes continue to escape, pure uranic oxide remains in the form of a chamois-yellow powder. When ammonio-uranic carbonate (i. 797), or uranic hydrate, is heated for some time to 300°, uranic oxide remains as a brick-red powder, according to Ebelmen; according to Malaguti, however, the oxide prepared by heating the hydrate always retains a certain quantity of water. Uranic oxide, when heated to redness, gives off oxygen and leaves green uranoso-uranic oxide.

Uranic hydrate cannot be prepared by precipitating a uranic salt with alkalis, inasmuch as the precipitate always carries down alkali with it. Pure uranic hydrate may be obtained:—1. By heating uranic nitrate contained in a covered vessel in the sand-bath as long as nitric acid is given off; uranic hydrate then remains, mixed with basic nitrate, from which it may be freed by boiling with water (Berzelius).—2. A solution of uranic nitrate in absolute alcohol is evaporated at a moderate heat till, at a certain degree of concentration, nitrous ether, aldehyde, and other vapours are given off with violent intumescence, and a spongy yellow mass remains, which, when washed with boiling water, leaves uranic hydrate (Malaguti, Compt. rend. xvi. 851).—3. By exposing recently precipitated and still moist uranoso-uranic hydrate to the air (Ebelmen).—4. By boiling ammonio-uranic carbonate with water, and leaving the powder thereby separated (which contains about 2 per cent. ammonia) for some time under an imperfectly closed bell-jar (Drenkmann).—5. By fusing uranoso-uranic oxide with chlorate of potassium, and boiling out the fused mass with water.

The hydrate obtained by either of these processes contains, when dried in the air at ordinary temperatures, 11·65 per cent. water, agreeing with the formula $U^2O^3.2H^2O$. In a vacuum at ordinary temperatures, or at 100° in the air, it gives off half its water, leaving the monohydrate, $U^2O^3.H^2O$, which contains 6·11—6·28 per cent. water (by calculation, 5·88 per cent.) (Ebelmen; Malaguti). According to Drenkmann, the dihydrate prepared by the last two processes does not give off the half of its water till heated to 160°.

The monohydrate has a lemon-yellow colour, inclining to orange-yellow, and a specific gravity of 5·92. It is permanent in the air, and does not absorb carbonic acid. According to Ebelmen, it gives off all its water at 300°; but according to Malaguti, it still retains two-thirds of its water at 400°, and when more strongly heated, gives off oxygen as well as water. At a red heat it is reduced to uranoso-uranic oxide.

Uranic oxide and its hydrates dissolve in acids, forming the uranic salts (p. 943).

Uranates.—Uranic oxide unites with basic metallic oxides, forming salts called uranates. The uranates of the alkali-metals are obtained by precipitating a uranic salt with a caustic alkali; those of the earth-metals and heavy metals, by precipitating a mixture of a uranic salt and a salt of the other metal with ammonia, or by igniting a double carbonate or acetate of uranium and the other metal (calcio-uranic acetate, for example) in contact with the air. The uranates have, for the most part, the composition $M^2O.2U^2O^3$. They are yellow, insoluble in water, soluble in acids. Those which contained fixed bases are not decomposed at a red heat; but at a white heat, the uranic oxide is reduced to uranoso-uranic oxide, or by ignition in hydrogen to uranous oxide; the mass obtained by this last method easily takes fire in contact with the air.

Uranate of Ammonium is precipitated from uranic salts by ammonia, as a yellow powder, which is slightly soluble in pure water, quite insoluble in water containing sal-ammoniac, is not decomposed at 100°, but at higher temperatures gives off nitrogen, ammonia, and water. This salt sometimes occurs in commerce as a fine deep yellow colour, called "uranium-yellow." It is easily prepared by adding chloride or sulphate of ammonium to a boiling solution of sodium-uranate as long as ammonia and ammonium-carbonate are given off, washing the resulting precipitate, and drying it at a gentle heat (Anthon, Ding. pol. J. clvi. 211). This salt, when heated to redness, leaves pure uranoso-uranic oxide, and may therefore serve as the raw material for the preparation of other uranium-compounds.

Uranate of Barium, $BaO.2U^2O^3$, obtained by precipitation, as above described, is yellowish-red or orange-yellow, and when ignited in hydrogen, leaves an inflammable mixture of uranoso-uranic oxide and baryta.—The *calcium-salt* is obtained in a similar manner. Many natural uranium-ochres consist of this compound, and in that case do not give off any oxygen at a red heat.—The *lead-salt*, $PbO.2U^2O^3$, obtained by precipitation, or by repeatedly boiling carbonate of lead with fresh quantities of uranic acetate, is yellowish-red, becoming brown-red by moderate ignition; when heated in a pottery-furnace it becomes straw-yellow without undergoing reduction, and is then difficult to dissolve in acetic acid; when ignited in hydrogen, it leaves a pyrophoric mixture of uranous oxide and metallic lead (Wertheim).—The *magnesium-salt*, $MgO.2U^2O^3$, obtained by igniting magnesio-uranic acetate, is a yellow-brown powder.

The *potassium-salt*, $K^2O.2U^2O^3.3H^2O$ (Patera), is prepared by precipitating a uranic salt with excess of caustic potash; or by igniting potassio-uranic carbonate or acetate; or by fusing uranic oxide with excess of potassium-carbonate, and washing out with water. When prepared in the wet way, it is a light orange-yellow powder; when obtained by ignition, yellowish-red. It is partially reduced by hydrogen, yielding a mixture of uranoso-uranic oxide with a more basic uranate of potassium (Berzelius; Wertheim). Uranate of potassium may also be prepared from pitchblende in the same manner as the sodium-salt (*infra*). An orange-coloured potassium-uranate is produced by precipitating a solution of potassio-uranic carbonate in carbonate of potassium with caustic potash, and is prepared on the large scale by roasting pitchblende, with subsequent addition of crude potash and saltpetre (Wysocki, Dingl. pol. J. clv. 305).—An *acid salt*, $K^2O.6U^2O^3.6H^2O$, is produced by fusing acid uranic sulphate with chloride of potassium; and remains, on lixiviating the fused mass, as a yellow powder composed of microscopic rhombic prisms. It becomes brick-red by prolonged heating, and silver-grey at a white heat, in consequence of the conversion of the uranic into uranoso-uranic oxide. (Drenkmann.)

The *silver-salt*, obtained by precipitation, or by boiling argento-uranic acetate with water, is a red powder which decomposes when heated above 100°.

Sodium-salts.—The *normal salt*, $Na^2O.U^2O^3$, obtained like the potassium-salt, is yellow, and exhibits characters similar to those of the potassium-salt. By fusing it with sodium-chloride, and lixiviating with water, another salt is obtained, probably $Na^2O.U^2O^3$, in yellow six-sided tables, mixed with a small quantity of uranoso-uranic oxide (Drenkmann). By fusing uranic nitrate with sodium-chloride, and lixiviating the cooled mass, an *acid uranate of sodium*, $Na^2O.3U^2O^3$, is obtained in bronze-coloured nacreous laminæ, resembling mosaic gold, and made up of microscopic rhombic tables. It has a specific gravity of 6·91, is insoluble in water, is decomposed only at a white heat, afterwards appearing silver-grey by reflected, colourless by transmitted light, and containing uranoso-uranic oxide. (Drenkmann.)

The normal salt, $Na^2O.2U^2O^3$, is much used for imparting a yellowish or greenish colour to glass, and as a yellow pigment on the glazing of porcelain. The "uranium-yellow" for these purposes is prepared on the large scale by roasting 100 pts. of finely-pulverised pitchblende (containing 45 per cent. uranoso-uranic oxide) with 14 pts. lime in a reverberatory furnace; treating the resulting uranate of calcium with dilute sulphuric acid, by which the uranic oxide is almost completely dissolved; mixing the green solution with crude sodium-carbonate, by which the uranium is precipitated, together with other metals, but redissolved, tolerably free from impurities, by excess of the alkali; and treating the liquid with dilute sulphuric acid as long as effervescence ensues. The sodium-uranate is then precipitated as a hydrate, which becomes crystalline when dry, and then contains $Na^2O.2U^2O^3.6H^2O$ (Patera, J. pr. Chem. lxi. 397). Glass coloured with uranium-yellow is highly fluorescent.

An orange-coloured uranate of sodium may be prepared by precipitating a solution of pure sodio-uranic carbonate with caustic soda, pressing, drying, and pulverising the precipitate, then washing it, and drying it again. (Wysocki.)

Uranate of Zinc is obtained by precipitating a mixture of uranic acetate and zinc-acetate with baryta-water, or by precipitating uranic nitrate with metallic zinc, being then deposited on the metal as a compact yellow coating. (Wertheim.)

URANIUM, SULPHIDES OF. The only sulphur-compounds of uranium hitherto obtained in definite form, are uranous sulphide, US, and uranous oxysulphide, U^2S^2O. Uranic sulphide, U^2S^3, is not known with certainty.

Uranous Sulphide, US, is produced with incandescence when metallic uranium is heated in sulphur-vapour (Péligot); quickly also, but without incandescence, when uranous chloride is heated to redness in sulphydric acid (Hermann). As thus prepared, it is a greyish-black amorphous powder, which becomes crystalline when heated to whiteness out of contact with air. Uranous sulphide is also formed as a black precipitate on adding sulphite of ammonium to a solution of uranous chloride or nitrate (Hermann). When exposed to moist air, it gradually gives off sulphydric acid, and is converted into a basic sulphate; when heated in the air, it gives off sulphurous oxide, and is converted into uranoso-uranic oxide. It is not decomposed by hot hydrochloric acid, but dissolves easily in the concentrated acid. Chlorine decomposes it rapidly; nitric acid converts it into uranic sulphate.

When an oxide of uranium is ignited in a mixture of carbonic dioxide and carbonic disulphide, the higher oxides are reduced to uranous oxide, but the latter undergoes no further decomposition. Uranous oxide, and not the sulphide, is likewise produced when uranous sulphate is heated in hydrogen-gas; or when a mixture of uranous oxide and sodium-uranate is ignited with flowers of sulphur and sal-ammoniac; or when uranous sulphate is heated with persulphide of potassium. (Hermann.)

Uranous Oxysulphide, $U^2S^2O = 2US.UO$, is produced, according to Hermann, when uranous or uranoso-uranic oxide is heated to bright redness in vapour of carbonic disulphide.

Uranic Oxysulphide, or *Sulphide of Uranyl*, is precipitated, according to Remelé (Compt. rend. lviii. 716), by sulphide of ammonium from a solution of uranic nitrate. It dissolves partially in cold water, forming a brown solution, which deposits uranic oxide on standing.

Uranic Sulphide has not been obtained in the separate state; but when the precipitate formed by sulphide of ammonium in uranic salts is left for a day or two in the liquid, it is converted into a blood-red compound containing ammonium-sulphide; and this compound, when treated with potash-ley, yields a red pulverulent body containing, according to Patera, $K^2S.2U^2S^3 + 21(K^2O.2U^2O^3.3H^2O)$. The red ammonium-compound treated with the chlorides of sodium, barium, and strontium, yields corresponding red compounds containing those metals. When boiled with lime or magnesia, it turns black. (Patera, Ann. Ch. Pharm. lxxxvi. 254.)

URANIUM-BLOOM. Syn. with Uraconise (*infra*).

URANIUM-GREEN. *Uran-grün. Uranochalcite.*—These names are applied to certain decomposition-products of uranium-ores, occurring thereon in small spherical masses, or in fine needle-shaped crystals, and consisting, according to Lindacker, of uranoso-uranic sulphate mixed with calcic and cupric sulphates.

URANIUM-MICA. Syn. with Uranite (p. 940).

URANIUM-OCHRE. *Uranochre. Earthy Hydruranite. Uranite terreux.*—A term applied to various earthy uranium-minerals, such as ochry uranic hydrate and basic uranic sulphates, occurring, with or without calcic sulphate, at Joachimsthal; the latter are also called *Uraconise*, or *Zippeite.*

URANIUM-ORANGE. Orange-coloured uranates of potassium and sodium (p. 948).

URANIUM-VITRIOL. A basic uranic sulphate containing 4·0 per cent. SO^3, 79·0 U^2O^3, and 14·3 water, occurring in lemon-yellow, microscopic, rhombic prisms, at Joachimsthal in Bohemia.

URANIUM-YELLOW. A term applied to uranate of sodium, used as a pigment, and to uranate of ammonium (p. 948).

URANOCHALCITE. Syn. with Uranium-green.

URANOCHRE. Syn. with Uranium-ochre.

URANONIOBITE. A term applied by Hermann (J. pr. Chem. lxxvi. 326) to crystallised pitchblende from Norway, containing a small quantity of niobic acid.

URANOPHANE. A mineral consisting of hydrated uranic silicate, together with many other constituents, found in a mine near Kupferberg in Silesia. (Handw. d. Chem. ix. 43.)

URANOPHYLLITE. Syn. with Uranite (p. 940).

URANOPISSITE. Syn. with Pitchblende (p. 946).

URANOTANTALITE. Syn. with Samarskite, or Uranoniobate of Yttrium and Iron (iv. 55; v. 186).

URANYL. U^2O^2.—A diatomic radicle, which may be supposed to exist in the uranic compounds (p. 942).

URAO. Tetrasodic carbonate, or sesquicarbonate of soda, $Na^4H^2(CO^3)^3.2H^2O$, occurring at the bottom of a lake in Maracaibo, South America (i. 796).

URARI. Syn. with Curara (ii. 185).

URATES. See Uric Acid (p. 956).

URDITE. A mineral of unknown composition, occurring in the orthoclase of Notteröe in Norway. It has been supposed to be identical with monazite (cerous phosphate); but, according to Forbes and Dahll (J. pr. Chem. lxvi. 445), it crystallises in triclinic forms, whereas monazite is monoclinic.

UREA. COH^4N^2. *Urée. Harnstoff. Urenoxyd-ammoniak.*—This substance, isomeric with ammonium-cyanate and with carbamide, and forming the chief organic constituent of human urine, was first obtained, in an impure state, as *Extractum saponaceum urinæ*, by Rouelle the younger, in 1773, and afterwards prepared, in a state of greater purity, by Fourcroy and Vauquelin, in 1799. Wohler, in 1828 (Pogg. Ann. xii. 253; xv. 619), obtained it by molecular transformation of ammonium-cyanate, and it has been further examined, chiefly by Liebig and Wohler (*ibid.* xx. 372), Dumas (Ann. Ch. Phys. [2], xliv. 273), Pelouze (*ibid.* [3], vi. 65), Marchand (J. pr. Chem. xxxiv. 248; xxxv. 481), Werther (*ibid.* xxxv. 51), Heintz (*ibid.* xlii. 401), and Millon (Compt. rend. xxvi. 119).

Urea is contained in the urine of all mammiferous animals, especially in that of the flesh-eaters; in smaller quantity also in that of birds and of reptiles; and in the renal secretions of some animals of the lower orders. It is found in small quantity in the blood of man and of other animals in the state of health; sometimes also in the perspiration, in the amniotic liquid, in morbid exudations, and even in the tissues. It forms an essential constituent of the vitreous humour of the eye (about 30 per cent. of the solid substance, according to Millon), and has lately been found by Wurtz (Ann. Ch. Pharm. xcviii. 287) in the chyle and lymph of various animals. Its presence in the animal economy is due to the transformation of the tissues under the influence of oxygen absorbed in respiration; it is, in fact, the last term in the series of organic products of oxidation of the nitrogenous tissues.

Urea is produced artificially:—1. By the spontaneous transformation of ammonium-cyanate. A solution of this salt, when recently prepared, exhibits the reactions of cyanic acid; but when heated, or left to evaporate, it is converted into urea. Sulphocyanate of ammonium heated with oxide of silver is first converted into cyanate of ammonium, and then into urea.—2. From cyanamide, CN^2H^2, by assumption of 1 at. water, the change taking place on adding a drop of nitric acid to the aqueous solution.

3. It is obtained as a product of the decomposition of many organic bodies of complex constitution: *e.g.*, of creatine, guanine, uric acid, allantoin, &c.

Urea is commonly regarded as identical with carbamide, $N^2\left\{\begin{matrix}(CO)''\\ H^4\end{matrix}\right.$; and, consequently, the processes which give rise to this latter compound are generally spoken of as modes of formation of urea. Such are the reactions of gaseous ammonia on chloride of carbonyl, of aqueous ammonia on ethylic carbonate (i. 752), and the decomposition of oxamide by heating with mercuric oxide (Williamson, *Mémoires du Congrès scientif. de Venise*, 1847):

$$\underset{\text{Oxamide.}}{N^2(C^2O^2)''H^4} + HgO = \underset{\text{Carbamide.}}{N^2(CO)''H^4} + CO^2 + Hg.$$

But urea, though it exhibits most of the characters of an amide, especially in being resolved into carbonic acid and ammonia by the action of acids and alkalis, nevertheless does not appear to react like an amide under all circumstances. Thus, it has been lately shown by Wanklyn and Gamgee (Chem. Soc. J. xxi. 25), that urea, when heated with a great excess of potassium-permanganate in presence of much caustic potash, gives off the whole of its nitrogen in the form of nitrogen-gas; whereas, when ammonium-salts and amides are similarly heated, the whole of the nitrogen is oxidised to nitric acid. Hence Wanklyn and Gamgee regard urea as constituted differently from carbamide, and represent it by the formula $C\left\{\begin{matrix}(NH)''\\ NH^2\\ OH\end{matrix}\right.$, which is that of marsh-gas having 2 at. hydrogen replaced by imidogen, one by amidogen, and the fourth by hydroxyl. Carbamide may be represented on the same type as $C\left\{\begin{matrix}NH^2\\ NH^2\\ O''\end{matrix}\right.$, and cyanate of ammonium as $C\left\{\begin{matrix}N'''\\ O(NH^4)\end{matrix}\right.$.

Preparation of Urea.—1. From urine.—The urine is evaporated to dryness over the water-bath; the residue is exhausted with alcohol; the solution again evaporated; and the residue exhausted with absolute alcohol: the resulting solution yields, by evaporation, slightly coloured urea.—Or urine concentrated by evaporation, or by leaving it to freeze, is treated with nitric or oxalic acid, which throws down a precipitate of nitrate or oxalate of urea. The oxalate may be decomposed by chalk, which forms insoluble calcic oxalate, leaving the urea in solution (Berzelius). The nitrate of urea is decomposed in aqueous solution by carbonate of barium or potassium; the greater part of the resulting nitrate of barium or potassium is removed by evaporation and crystallisation; and the urea remaining in solution is purified by repeated crystallisation from alcohol.

2. From **cyanate of ammonium**.—The artificial preparation of urea from this salt yields a much better product than the preparation from urine. Cyanate of potassium is decomposed by sulphate of ammonium, and the resulting sulphate of potassium, which is very little soluble either in water or in alcohol, is separated from the urea formed by transformation of the ammonium-cyanate, which is very soluble in both liquids.

The following methods give good results:—*a.* A mixture of 28 pts. dry and pulverised ferrocyanide of potassium and 14 pts. manganese-peroxide is heated on an iron plate; the solution obtained by exhausting the mass with cold water is mixed with 20½ pts. dry sulphate of ammonium; the liquid is decanted from the precipitated sulphate of potassium; and the remaining portion of that salt is removed, as far as possible, by evaporation and cooling. The solution is then evaporated to dryness, and the urea is extracted from the residue by boiling alcohol (**Liebig**).—*β.* Cyanide of potassium, prepared by melting 8 pts. of the dehydrated ferrocyanide with 3 pts. carbonate of potassium, is converted into cyanate by adding 15 pts. minium to the melted mass. This salt is then dissolved out by water; the solution is mixed with 8 pts. sulphate of ammonium; the sulphate of potassium is removed as before; the filtered liquid is evaporated to dryness; and the residue is exhausted with boiling alcohol (**Clemm**, Ann. Ch. Pharm. lxvi. 382). The alcoholic solution of urea obtained by either of these methods frequently contains a certain portion of undecomposed ferrocyanide, which, however, may be easily removed by careful addition of ferrosoferric sulphate.—*γ.* According to **J. Williams** (Chem. Soc. J. xxi. 64), a better and more abundant product is obtained by digesting cyanate of lead, at a gentle heat, with an equivalent quantity of ammonium-sulphate, and evaporating the filtered liquid.

Properties.—From a pure aqueous solution, urea generally crystallises in long flattened prisms without terminal faces; but when the alcoholic mother-liquors, still containing a few impurities, are left to evaporate, the urea is obtained in slightly yellowish quadratic prisms, terminated by octahedral faces. Frequently the combination ∞P . P . oP is found at only one extremity of the prism. Angle ∞P : ∞P = 90°; ∞P : P = 139°; P : P = 82°; ∞P : oP = 90°. Urea has a cooling taste, like that of saltpetre. It dissolves in its own weight of cold water, in all proportions of hot water, and is also very soluble in alcohol (in 5 pts. of cold and 1 pt. of boiling alcohol), but nearly insoluble in ether. It melts at 120°, and decomposes at higher temperatures.

Decompositions.—1. Under various circumstances urea takes up water, and is resolved into carbonic anhydride and ammonia:

$$COH^4N^2 + H^2O = CO^2 + 2NH^3.$$

This decomposition takes place when urea is heated with *water* in sealed tubes to temperatures above 100°; or when it is boiled with *potash*, *lime*, or *magnesia*, or warmed with strong *sulphuric acid*, or evaporated with solution of *lead-acetate*; also under the influence of *ozone*, in presence of free alkali (**Gorup-Besanez**, Ann. Ch. Pharm. cxxv. 307); also by *electrolysis*. (**Schlagdenhauffen**, J. Pharm. [3], xliv. 100.)

2. In many cases urea gives up only half its nitrogen in the form of ammonia, the other half taking the form of cyanic or cyanuric acid:

$$COH^4N^2 = COHN + NH^3.$$

Thus a solution of urea evaporated with *nitrate of silver*, yields cyanate of silver and nitrate of ammonium (**Wöhler** and **Liebig**).—Urea heated with *phosphoric anhydride* yields phosphate of ammonium and cyanic acid, together with cyanuric acid, ammelide, &c.—Urea heated alone to 150°—170° is converted into biuret and cyanuric acid:

$$\underset{\text{Urea.}}{2COH^4N^2} = \underset{\text{Biuret.}}{C^2O^2H^5N^3} + NH^3.$$

$$\underset{\text{Urea.}}{3COH^4N^2} = \underset{\substack{\text{Cyanuric}\\\text{acid.}}}{C^3O^3H^3N^3} + 3NH^3.$$

But if the temperature be kept down to a few degrees above the melting-point, a white amorphous residue is obtained, consisting, according to **Gerhardt** (*Traité*, i. 406), of melanurenic acid (Gerhardt's ammeline):

$$\underset{\text{Urea.}}{4COH^4N^2} = \underset{\substack{\text{Melanurenic}\\\text{acid.}}}{C^3O^2H^4N^4} + CO^2 + 4NH^3.$$

Urea heated to 145°—160° with *phenol* also yields biuret, together with phenate of ammonium. (**Baeyer**, Ann. Ch. Pharm. cxxxi. 251.)

Hydrochlorate of urea heated to 145° yields chloride of ammonium and cyanuric acid. (**De Vry**, Ann. Ch. Pharm. lxi. 249.)

[illegible] the same [illegible] estimating [illegible]

[illegible] the weight of the [illegible] gives the [illegible]

[illegible] Ann. Ch. Pharm. lxxxv. [illegible] is based upon the [illegible] circumstance that the [illegible] is not decomposed, and therefore not turned yellow, by carbonate of sodium. 2 vols. urine are mixed with 1 vol. of a baryta-solution prepared with 2 vols. baryta-water saturated in the cold, and 1 vol. of a solution of barium-nitrate also saturated in the cold; the liquid is filtered from the precipitated sulphate and phosphate of barium; and a graduated solution of mercuric nitrate is added to a measured quantity of this filtered liquid (about 15 c.c.) till a sample taken out gives a yellow precipitate with carbonate of sodium. It is convenient to dilute the mercuric solution to such a degree that 1 cubic centimetre of it shall correspond to 0·01 grm. of urea.

Bunsen's method and that of Ragsky and Heintz give very exact results; those obtained by Millon's and Neubauer's methods are less satisfactory. Liebig's volumetric method is easy and quick of execution, and the results are very exact, when certain necessary corrections are made. (See URINE, p. 966.)

Compounds of Urea.

α. **With Acids.**—*Hydrochlorate of urea*, $COH^4N^2.HCl$, is produced, with evolution of heat, by the action of hydrochloric acid gas on urea. The product is a yellow oil, which solidifies to a crystalline mass on cooling. It is decomposed by water, and even by moist air, and is resolved by heat (at 145°) into sal-ammoniac and cyanuric acid (p. 952).

Nitrate, $COH^4N^2.HNO^3$.—This salt, the most characteristic of the urea-compounds, is moderately soluble in water, but only very slightly soluble in nitric acid. Hence a crystalline precipitate is obtained on adding nitric acid to moderately dilute solutions of urea, and a concentrated solution solidifies with nitric acid to a crystalline pulp. Nitrate of urea separates in these precipitations in shining laminæ, which appear under the microscope as rhombic or hexagonal plates, the acuter angle of which = 82°. By slow evaporation, or by cooling of a warm aqueous solution, it is sometimes obtained in well-defined prisms. It is more soluble in hot than in cold water, and dissolves also in alcohol. It is decomposed by heat (at about 140°), and detonates when suddenly heated.

Oxalate, $2COH^4N^2.C^2O^4H^2$.—This salt separates in thin crystalline laminæ, mostly grouped in tufts, when a solution of urea is mixed with a concentrated solution of oxalic acid. It dissolves easily in hot water, less easily in cold water, still less in alcohol: it is precipitated from its aqueous solution by excess of oxalic acid.

According to **Loschmidt** (Wien. Akad. Ber. li. [2], 7, 384), oxalate of urea crystallises in monoclinic usually tabular prisms, exhibiting the combination [∞P∞] . oP . ∞P . [∞P2] . [P∞] . +P . +2P∞ . Axes *a* : *b* : *c* = 1 : 0·56415 : 0·49062. Angle *b* : *c* = 82° 10′; [∞P∞] : ∞P = 112° 12′; oP : +2P∞ = 119° 4′; ∞P : +2P∞ = 134° 16′. The crystals cleave perfectly parallel to +2P∞ .

The crystalline forms of several other urea-salts have also been examined by **Loschmidt** (Wien. Akad. Ber. lii. [2], 238; Jahresb. 1865, p. 657).—The *fumarate*, $2COH^4N^2.C^4H^4O^4$, *acid maleate*, $COH^4N^2.C^4H^4O^4$, *neutral maleate*, $2COH^4N^2.C^4H^4O^4$, *acid malate*, $COH^4N^2.C^4H^6O^5$, and *succinate*, $2COH^4N^2.C^4H^6O^4$, crystallise in monoclinic forms; the *gallate*, $COH^4N^2.C^7H^6O^5$, in monoclinic but nearly rectangular prisms; the *parabanate*, $COH^4N^2.C^3H^2N^2O^3$, and the *tartrate*, $2COH^4N^2.C^4H^6O^6$, in rhombic forms; and the *citrate*, $2COH^4N^2.C^6H^8O^7$, in shining, six-sided, triclinic prisms.

β. **With Metallic Oxides.**—On adding moist *silver-oxide* to a solution of urea, a grey powder is deposited, made up of fine needles, and containing $2COH^4N^2.3Ag^2O$.

Mercuric nitrate added to a solution of urea mixed with potash, forms a white precipitate containing $COH^4N^2.2HgO$.—*Mercuric chloride* forms in the same solution a white precipitate, $2COH^4N^2.3HgO$, which turns yellow in boiling water. On adding mercuric oxide to a warm solution of urea, the compound $COH^4N^2.HgO$ appears to be produced.

γ. **With Salts.**—A solution saturated in the cold with equivalent quantities of urea and *sodium-chloride*, yields, on evaporation, shining, well-developed, monoclinic prisms of the compound $COH^4N^2.NaCl.H^2O$.—A boiling very concentrated aqueous solution of 1 at. *sodium-nitrate* mixed with 1 at. urea, deposits, on cooling, long prismatic crystals of the compound $COH^4N^2.NaNO^3.H^2O$. Urea likewise forms crystallisable compounds with the nitrates of potassium, calcium, and magnesium, chloride of cadmium, and mercuric chloride.

With *nitrate of silver*, urea forms the two compounds, $COH^4N^2.AgNO^3$ and $COH^4N^2.2AgNO^3$. The former is obtained in large rhombic prisms, when solutions of urea and silver-nitrate are mixed together, either cold or warm. The second separates in prismatic crystals, by evaporation in a vacuum, from a solution containing an excess of the silver-salt.

δ. **With Nitric Anhydride and Mercuric Oxide.**—Mercuric nitrate added to a solution of urea forms a white precipitate, the composition of which varies according to circumstances. When the two solutions are dilute, and mixed while warm, the flocculent precipitate formed at first quickly changes to a white granular powder containing $2COH^4N^2.N^2O^5.4HgO$. When a solution of silver-nitrate is poured into a solution of urea as long as a precipitate is formed, and this precipitate is exposed for some time to a temperature of 40°—50°, it is transformed into a mass of six-sided shining laminæ, consisting of $2COH^4N^2.N^2O^5.3HgO$. Lastly, when a solution of nitrate of urea is mixed with an acid solution of mercuric nitrate till turbidity ensues, the liquid deposits, on standing, crystalline crusts made up of small tabular crystals of the compound $COH^4N^2.N^2O^5.2HgO$. (Liebig.)

The composition of these three compounds is not yet definitely fixed; it is not known, indeed, whether they contain mercuric oxide and nitrate of urea, or urea combined with mercuric nitrate and mercuric oxide.

Substitution-derivatives of Urea.—Compound Ureas.

These bodies have already been described as carbamides (i. 753). They must, however, be regarded as derivatives of urea, not of carbamide, if carbamide and urea are really distinct compounds; for those which contain acid radicles are produced by the action of acid chlorides upon urea itself; and those containing alcohol-radicles are obtained by processes exactly analogous to those which yield normal urea—viz., by the action of ammonia on cyanic ethers, or of amine-bases on cyanic acid or cyanic ethers. Corresponding derivatives of carbamide might be produced by the action of amines on phosgene or on carbonic ethers, but the reaction does not appear to have been tried.

Ureas containing two atoms of alcohol-radicle are likewise formed by the action of water on cyanic ethers, an amine being produced in the first instance, and then combining with the rest of the cyanic ether; thus:

$$\underset{\substack{\text{Ethylic}\\\text{cyanate.}}}{CO(C^2H^5)N} + H^2O = CO^2 + \underset{\text{Ethylamine.}}{(C^2H^5)H^2N}.$$

$$\underset{\substack{\text{Ethylic}\\\text{cyanate.}}}{CO(C^2H^5)N} + (C^2H^5)H^2N = \underset{\text{Diethylurea.}}{COH^2(C^2H^5)^2N^2}.$$

Diethylurea is also produced by distilling the oily body, $C^8H^{17}N^3O^3$, formed by the action of potash on cyanuric ether (ii. 293):

$$C^8H^{17}N^3O^3 = \underset{\substack{\text{Ethylic}\\\text{cyanate.}}}{CO(C^2H^5)N} + \underset{\text{Diethylurea.}}{COH^2(C^2H^5)^2N^2}.$$

Polymeric ureas containing ethylene are produced by the action of cyanic acid or the cyanic ethers on ethylene-diamines (ii. 595):

$$\underset{\substack{\text{Chloride of ethy-}\\\text{lene-diammonium.}}}{(C^2H^4)''H^6N^2Cl^2} + \underset{\substack{\text{Cyanate of}\\\text{silver.}}}{2COAgN} = 2AgCl + \underset{\text{Ethylene-urea.}}{C^2O^2H^6(C^2H^4)''N^4}.$$

The properties and reactions of the compound ureas are analogous to those of urea itself. They mostly crystallise in deliquescent prisms, easily soluble in water and in alcohol. They form crystallisable compounds with nitric acid, but on the whole do not unite with acids so easily as normal urea. Those which contain only 1 at. alcohol-radicle are resolved by heat into cyanic acid and an amine-base. Dimethylurea and diethylurea are volatile without decomposition; or, rather, they are reproduced, during the distillation, by the combination of the products (cyanuric ether and ethylamine, for example) resulting from their decomposition in the earlier stage of the process.

UREIDES. Compounds containing the elements of a urea-salt minus water. (See URIC ACID, p. 958.)

URET. This name has been applied to the group CH^2NO, which, by substitution for 1 at. hydrogen in ammonia, may be supposed to form urea, $\left.\begin{matrix}CH^2NO\\H^2\end{matrix}\right\}N$, and by substitution for 2 at. hydrogen, biuret, $\left.\begin{matrix}(CH^2NO)^2\\H\end{matrix}\right\}N$ (i. 600).

URETHAMYLANE. Syn. with AMYLIC CARBAMATE.

URETHANE. A name first applied to ethylic carbamate, afterwards extended to all carbamic ethers (i. 750).

URETHYLANE. Syn. with METHYLIC CARBAMATE.

URIC ACID. $C^5N^4H^4O^3$. *Lithic acid. Harnsäure.*—This important acid was discovered by Scheele in 1776, but was first submitted to a minute examination by

Liebig and Wöhler in 1838 (Ann. Ch. Pharm. xxvi. 241). Its reactions and transformations have also been examined by Brugnatelli (Ann. Ch. Phys. [2], viii. 201), who discovered alloxan; by Prout (Ann. Phil. xiv. 363), who discovered murexide; further by Gregory (Ann. Ch. Pharm. xxxiii. 334; lx. 267), Schlieper (*ibid.* lv. 252; lvi. 1; lxvii. 231), Pelouze (Ann. Ch. Phys. [3], vi. 71), and, more especially of late years, by Baeyer (Ann. Ch. Pharm. cxxvii. 199; cxxx. 129; cxxxv. 312; Jahresb. 1863, p. 621; 1864, p. 632; 1865, p. 362), who has discovered a considerable number of new derivatives of uric acid, and given the most complete and connected account of the uric acid group of compounds yet published.

Uric acid is a product of the incomplete oxidation of animal tissue. In combination chiefly with ammonia, it forms the principal urinary constituent voided by insects, land-reptiles, and birds (whence it is found in guano). Normally it occurs, but in small proportion, in the urine of man, and is found in yet smaller proportions in that of carnivorous quadrupeds, and can scarcely be said to exist in that of herbivorous and omnivorous quadrupeds.

According to various authorities, it is constantly present in the juices of the human spleen, liver, lungs, and brain. The merest traces of it are also met with normally in blood; but in certain forms of disease, such as albuminaria, and more especially gout, its proportion in the blood becomes very appreciable. In certain cases of gout, indeed, all the fluids of the body are found more or less saturated with uric acid, and some of them even supersaturated, so as to deposit the concretions of sodium-urate, commonly known as chalk-stones. Lastly, the excess of it, occurring under greater or less derangement of bodily health, is frequently discharged by the kidneys, and deposited in the form of urinary sediment, gravel, or calculus.

No artificial method of producing uric acid has yet been discovered.

Preparation.—The best material for preparing uric acid is the excrement of serpents. This substance, which consists chiefly of ammonium-urate, is boiled with dilute potash or soda-ley, till completely dissolved; and the filtered solution is supersaturated with hydrochloric or dilute sulphuric acid, whereby the uric acid is thrown down as a flocculent gelatinous precipitate, which soon becomes crystalline. Potash is better adapted for the purpose than soda, because urate of potassium is much more soluble than urate of sodium.

Uric acid may also be prepared from guano, by boiling that substance with a dilute solution of borax (1 pt. borax to 120 pts. water), whereby a solution of sodium-urate is obtained, and precipitating with hydrochloric acid.

Properties.—Uric acid precipitated by hydrochloric acid is anhydrous, and forms small perfectly white crystalline scales. When slowly deposited from dilute solutions, it sometimes separates in large crystals containing $C^5H^4N^4O^3.2H^2O$. It is nearly insoluble in *water*, 1 pt. of it requiring 15,000 pts. of cold and 1,800 pts. of boiling water to dissolve it; in *alcohol* and *ether* it is quite insoluble. Concentrated *sulphuric acid* dissolves it abundantly when heated, and the solution, on cooling, deposits a very deliquescent compound, containing $C^5N^4H^4O^3.4SO^4H^2$, according to Fritzsche; $C^5N^4H^4O^3.2SO^4H^2$, according to Lowe (Bull. Soc. Chim. 1867, i. 442). Water added to the solution precipitates the uric acid.

Decompositions.—1. Dry uric acid, when heated, decomposes without melting, giving off hydrocyanic acid, yielding a sublimate of cyanuric acid, cyanate of ammonium, urea, and carbonate of ammonium, and leaving a carbonaceous residue.—Uric acid heated with *water* for some time to 180°, undergoes a decomposition, the chief product of which is mycomelic acid (Hlasiwetz, Ann. Ch. Pharm. ciii. 211):

$$C^5N^4H^4O^3 = C^4N^4H^4O^2 + CO.$$

An alkaline solution of uric acid boiled for a considerable time yields uroxanic acid, together with formic acid, oxalic acid, and urea.—3. Uric acid fused with *hydrate of potassium*, gives off ammonia, and leaves a residue containing oxalate, carbonate, and cyanate of potassium.

4. Dry uric acid is not attacked by dry *chlorine* at ordinary temperatures, but when heated in the gas, it is decomposed, yielding cyanic acid together with other products. When chlorine acts upon uric acid in presence of water, alloxan and parabanic acid are produced in the first instance, and ultimately carbonic acid, oxalic acid, and ammonia. According to L. Hardy (Ann. Ch. Phys. [4], ii. 372), uric acid suspended in water is converted by *bromine*, at ordinary temperatures, into alloxan and urea:

$$C^5N^4H^4O^3 + Br^2 + 2H^2O = C^4N^2H^2O^4 + CN^2H^4O + 2HBr.$$

If the mixture becomes heated during the reaction, parabanic acid, oxalic acid, and bromide of ammonium are likewise produced. *Chlorine* and *iodine* act in like manner.

Most *oxidising substances* convert uric acid into alloxan or parabanic acid; when boiled with *water* and *peroxide of lead*, it yields allantoin.—With *chlorous acid*, it yields, according to **Schiel** (Ann. Ch. Pharm. cxli. 78), a chlorinated acid called **chloraluric acid** (i. 884).—*Ozone* is quickly absorbed by uric acid, forming allantoin and urea, together with other products (**Gorup-Besanez**, *ibid.* cx. 433). Uric acid boiled with a solution of *potassium-ferricyanide* containing caustic potash, yields carbonate of potassium and allantoin, part of which is ultimately converted into lantanuric acid and urea.

Detection and Estimation.—Uric acid may be recognised by its insolubility in water and in hydrochloric acid, and by its crystalline character under the microscope (generally rhombic tables with the obtuse angles rounded off, and often associated with dumbbell-shaped crystals*), and especially by its reaction with *nitric acid.* On moistening it with nitric acid, and evaporating at a gentle heat, a yellow or reddish residue is obtained, which assumes a fine violet-red colour when treated with ammonia, and violet-blue with potash (murexide and purpurate of potassium, iv. 748). Another very delicate reaction is given by **Schiff** (Ann. Ch. Pharm. cix. 65). The uric acid is dissolved in *carbonate of sodium*, and a drop of the solution is laid on paper moistened with *silver-solution;* if uric acid is present, a brown spot is formed, carbonate of silver being reduced by uric acid at ordinary temperatures.

For the quantitative estimation of uric acid in urine, the liquid is mixed with hydrochloric acid, and left to stand for twenty-four hours, and the pulverulent deposit of uric acid is weighed. (See URINE, p. 967).

Urates.—Uric acid is dibasic. Its salts are but sparingly soluble in water, much more easily in alkaline liquids, especially when heated, freely soluble also in solutions of borax. They have been examined chiefly by **Bensch** (Ann. Ch. Pharm. liv. 189; lxv. 181).

Acid urate of ammonium, $C^5N^4H^3(NH^4)O^3$, is produced whenever uric acid and ammonia come in contact, and usually forms a white amorphous mass, but is deposited in fine needles from a solution containing excess of ammonia. It dissolves in 1,800 pts. of cold water. This salt occurs, together with free uric acid, in the excrements of birds and serpents. The neutral ammonium-salt is not known.

Potassium-salts.—The *neutral salt*, $C^5N^4H^2K^2O^3$, is obtained by saturating a cold dilute solution of potash, free from carbonate, with uric acid, and boiling down the solution in a retort. At a certain degree of concentration, the salt is deposited in fine anhydrous needles, which may be purified by decanting the clear liquid and washing with dilute alcohol. It dissolves in 44 pts of cold and 35 pts. of boiling water; the solution is slowly decomposed by boiling. The salt has a caustic taste, and quickly absorbs carbonic acid from the air.—The *acid salt*, $C^5N^4H^3KO^3$, is precipitated in a granular form on passing carbonic acid gas through a solution of the neutral salt. It dissolves in 800 pts. of cold and in about 80 pts. of boiling water, from which solution it is deposited, on cooling, in amorphous flocks.

There are two *urates of sodium*—the *neutral salt*, containing $C^5N^4H^2Na^2O^3.H^2O$ and the *acid salt*, $C^5N^4H^3NaO^3$. Both are less soluble than the corresponding potassium-salts.

Urate of Lithium is more soluble than any of the other alkaline urates: hence lithia-water is sometimes proscribed to gouty patients, and others who suffer from a superabundance of that acid.

Urates of Barium.—The *neutral salt*, $C^5N^4H^2Ba''O^3$, is obtained by adding uric acid to a boiling saturated solution of baryta, keeping the latter in excess. One pt. of it dissolves in 7,900 pts. of cold and 1,790 pts. of boiling water.—The *acid salt*, $C^{10}N^8H^6Ba''O^6$, produced by boiling uric acid with water and carbonate of barium, is a white powder, insoluble in water and in alcohol.

Urates of Strontium.—These salts are prepared like the barium-salts.—The *neutral salt*, $C^5N^4H^2Sr''O^3.2H^2O$, appears under the microscope as a mass of fine needles grouped in stars. It absorbs moisture from the air; gives off its water of crystallisation at 165°; decomposes at 170°; dissolves in 4,300 pts. of cold and 1,790 pts. of boiling water.—The *acid salt*, $C^{10}N^8H^6Sr''O^6.2H^2O$, is white, amorphous, insoluble in alcohol and in ether. One pt. of it dissolves in 603 pts. of cold and 276 pts. of boiling water.

Urates of Calcium.—The *neutral salt*, $C^5N^4H^2Ca''O^3$, is obtained by dropping a solution of the neutral potassium-salt into a boiling solution of calcium-chloride till a permanent precipitate begins to form, and boiling the solution for an hour; urate of calcium is then deposited in anhydrous grains, soluble in 1,500 pts. of cold and 1,440 pts. of boiling water.—The *acid salt*, $C^{10}N^8H^6Ca''O^6.2H^2O$, separates, on mixing chloride of calcium with a boiling solution of acid urate of potassium, as an amorphous precipitate, soluble in 603 pts. of cold and 276 pts. of boiling water, much more soluble in water containing chloride of potassium.

---

* These crystals have been supposed to consist of ammonium-oxalurate, but their nature has not been exactly ascertained.

Urate of Magnesium.—The neutral salt is not known.—The *acid salt*, $C^{10}N^8H^6Mg''O^6.6H^2O$, separates, after two or three hours, from a mixture of magnesium-sulphate and acid potassium-urate, in silky nodules, which often float at the surface of the liquid. The solution of these nodules in boiling water deposits needles, which at 170° give off 19·2 per cent. water of crystallisation, corresponding to rather less than 5 at. H^2O.

Urates of Copper.—The *cupric salt* is a green precipitate, which turns brown when boiled with water. A solution of uric acid in potash produces, in an alkaline cupric solution, a white crystalline precipitate of *cuprous urate*, which is permanent in the air, is decomposed by hydrochloric acid, yielding uric acid and cuprous chloride, does not undergo any alteration in hot water or potash-ley, but when boiled with the alkaline cupric solution, is converted into red cuprous oxide (Berlin, J. pr. Chem. lxxxi. 184). Babo and Meissner (Jahresb. 1858, p. 639) have applied this reaction to the volumetric estimation of uric acid; but the results do not appear to be very trustworthy.

Urate of Lead, $C^{10}N^8H^6Pb''O^6$, is obtained—by dropping a dilute solution of neutral potassium-urate into a boiling dilute solution of lead-nitrate, separating the yellow precipitate which first forms, and adding a fresh portion of the potassium-salt to the filtrate—as a white amorphous precipitate, apparently anhydrous, and quite insoluble in water and in alcohol.

Urate of Silver is a white amorphous precipitate, which quickly suffers reduction.

ETHYLURIC ACIDS. (Drygin, Jahresb. 1864, p. 630.)—Neutral urate of lead heated with excess of ethylic iodide to 100° for 24 hours, or to 120° for 12 hours, yields—together with iodide of lead—two ethylic derivatives of uric acid: namely, diethyluric acid, $C^5N^4H^2(C^2H^5)^2O^3$, and triethyluric acid, $C^5N^4H(C^2H^5)^3O^3$, which may be separated by cold ether-alcohol, the latter only dissolving therein.

Diethyluric acid, the most abundant product of the reaction, dissolves in water and in alcohol, but not in ether, remains as an amorphous mass when its alcoholic solution is evaporated, and crystallises from hot water in broom-shaped groups of short obtuse needles, which sublime with difficulty. It dissolves in cold potash-ley, and is precipitated therefrom by hydrochloric acid, in amorphous flocks which turn red after some time. It is decomposed by heating with dilute hydrochloric acid, but the products have not been examined. Iodide of ethyl converts it into the triethylated compound.

Triethyluric acid is soluble in ether, alcohol, and hot water, crystallises in small slender needles, melts when carefully heated, and sublimes very easily. It dissolves in potash, and is precipitated therefrom by hydrochloric acid in white needles. When heated with hydrochloric acid it gives off gas, and yields a product having the composition, but not the properties, of diethyluric acid.

Products formed from Uric Acid by Oxidation, &c.

Uric acid is remarkable for the facility with which it is altered by oxidising agents, and the great number of definite and crystallisable compounds obtained in this manner, or by treating the immediate products of oxidation with acids, alkalis, reducing agents, &c. The following is a list of the principal compounds thus produced:—

Uric acid . .	$C^5N^4H^2O^3.H^2$	Thionuric acid .	$C^4N^3H^3O^6S.H^2$
Pseudo-uric acid	$C^5N^4H^5O^4.H$	Hydurilic acid .	$C^4N^4H^4O^6.H^2$
Uroxanic acid .	$C^5N^4H^8O^6.H^2$	Allantoin . .	$C^4N^4H^6O^3$
Alloxan . .	$C^4N^2H^2O^4$	Glycoluril . .	$C^4N^4H^6O^2$
Alloxanic acid .	$C^4N^2H^2O^5.H^2$	Mycomelic acid .	$C^4N^4H^3O^2.H$
Alloxantin .	$C^8N^4H^4O^7.3H^2O$	Oxaluric acid .	$C^3N^2H^3O^4.H$
Barbituric acid .	$C^4N^2H^2O^3.H^2$	Allanturic acid .	$C^3N^2H^3O^3.H$
Bromobarbituric acid	$C^4N^2H^2BrO^3.H$	Hydantoin . .	$C^3N^2H^4O^2$
Dibromobarbituric acid	$C^4N^2H^2Br^2O^3$	Hydantoic acid .	$C^3N^2H^5O^3.H$
		Allituric acid .	$C^6N^4H^5O^4.H$
Violuric acid .	$C^4N^3H^2O^4.H$	Leucoturic acid .	$C^6N^4H^3O^5.H$
Dilituric acid .	$C^4N^3H^2O^5.H$	Parabanic acid .	$C^3N^2H^2O^3$
Violantin . .	$C^4N^6H^6O^9$	Dibarbituric acid .	$C^8N^4H^4O^5.H^2$
Dialuric acid .	$C^4N^2H^3O^4.H$	Murexide . .	$C^8N^6H^8O^6$
Uramil . .	$C^4N^3H^5O^3$	Mesoxalic acid .	$C^3O^5H^2$

When uric acid is subjected to an oxidising agent, in presence of water, it gives up two of its hydrogen-atoms to the oxidising agent, while the dehydrogenised residue (which may be called **dehyduric acid**) reacts with water to form **mesoxalic acid** and **urea**:

$$C^5N^4H^2O^3 + 4H^2O = \underset{\text{Mesoxalic acid.}}{C^3H^2O^5} + \underset{\text{Urea.}}{2CN^2H^4O.}$$

Dehyduric acid.

The separation of the urea generally takes place, however, by two stages, the first portion being removed more easily than the second; thus, when dilute nitric acid acts upon uric acid, alloxan is produced; and this, when heated with baryta-water, is further resolved into mesoxalic acid and urea:

$$\underset{\text{Dehyduric acid.}}{C^5N^4H^2O^3} + 2H^2O = \underset{\text{Alloxan.}}{C^4N^2H^2O^4} + \underset{\text{Urea.}}{CN^2H^4O.}$$

$$\underset{\text{Alloxan.}}{C^4N^2H^2O^4} + 2H^2O = \underset{\text{Mesoxalic acid.}}{C^3H^2O^5} + \underset{\text{Urea.}}{CN^2H^4O.}$$

Moreover, the urea is frequently resolved into carbonic acid and ammonia by the action of the acids or alkalis present.

Alloxan is a monureide of mesoxalic acid—that is to say, it is a compound of that acid with one atom of urea minus $2H^2O$; and the hypothetical dehyduric acid is the diureide of the same acid, derived from it by addition of 1 at. urea and subtraction of 4 at. water. Now, by hydrogenising mesoxalic acid, we obtain **tartronic acid**, $C^3H^4O^5$; and by hydrogenising alloxan, we obtain **dialuric acid**, which two bodies, accordingly, bear to uric acid the same relation that mesoxalic acid and urea bear to dehyduric acid: thus—

$C^3H^2O^5.$	$C^4N^2H^2O^4.$	$C^5N^4H^2O^3.$
Mesoxalic acid.	Alloxan.	Dehyduric acid.
$C^3H^4O^5.$	$C^4N^2H^4O^4.$	$C^5N^4H^4O^3.$
Tartronic acid.	Dialuric acid.	Uric acid.

And just as the hypothetical dehyduric acid yields mesoxalic acid and alloxan, so should actual uric acid yield tartronic and dialuric acids. These bodies, however, have not been obtained by the direct breaking-up of uric acid, but only by rehydrogenising the mesoxalic acid and alloxan which result from the breaking-up of its dehydrogenised product.

Provisionally, however, dialuric and uric acids may be regarded as tartron-ureide and tartron-diureide, respectively.

The several bodies just mentioned are typical of three well-defined classes of compounds, to one or other of which an immense number of uric acid products may be referred. First, there is the class of simple non-nitrogenous acids, or **an-ureides**, like tartronic and mesoxalic acid; secondly, there is a class of bodies containing a residue of the acid plus one residue of urea—these are the **mon-ureides**, such as dialuric acid and alloxan; and, lastly, the class of bodies containing a residue of the acid plus two residues of urea, or the **di-ureides**, such as uric acid itself.

Mesoxalic acid, the most complex non-nitrogenous product obtainable directly from uric acid, constitutes the third term in the following series:

An-ureides.

CH^2O^3, Carbonic acid,
$C^2H^2O^4$, Oxalic acid,
$C^3H^2O^5$, Mesoxalic acid,

each of which contains 1 at. carbonic oxide, CO, more than the preceding. Now, when mesoxalic acid is acted upon by nascent oxygen, its excess of carbonic oxide is removed in the form of carbonic dioxide, and it is thus converted into oxalic acid:

$$\underset{\text{Mesoxalic acid.}}{C^3H^2O^5} + O = CO^2 + \underset{\text{Oxalic acid.}}{C^2H^2O^4.}$$

Hence, when uric acid is subjected to a more active oxidation than that which suffices to produce mesoxalic acid, we obtain oxalic acid, which may occur either in its simple anureide state, or conjugated with 1 at. urea to form a monureide, such as **parabanic acid**; or with 2 at. urea to form a diureide, such as **mycomelic acid**, a body related to oxalic acid just as uric acid is related to mesoxalic acid.

In like manner, when uric acid is subjected to a still more powerful oxidation than suffices to produce oxalic acid, we obtain carbonic acid, which, like oxalic and mesoxalic acids, is also capable of giving rise to ureides. No ureide of carbonic acid has, indeed, yet been formed directly from uric acid, the active treatment required to effect the complete oxidation of the uric acid producing also a separation from one another of the resulting carbonic acid and urea, which, however, may be obtained in combination by other means. Allophanic acid, for instance, is a monureide of carbonic acid; but no diureide of this acid appears to have been yet produced.

Alloxan, the monureide of mesoxalic acid above mentioned, is formed from mesoxalate of urea by elimination of 2 at. water; but there is another monureide, namely alloxanic acid, which differs from the original salt by only 1 at. water. Similarly, oxalic acid forms two monureides—namely, parabanic acid or paraban, analogous to alloxan; and oxaluric acid, analogous to alloxanic acid. Carbonic acid, however, forms but a single ureide, which is produced by the elimination of only 1 at. water, and accordingly belongs to the same series as the oxaluric and alloxanic acids: thus—

Acids.	*Ureides.*
CH^2O^3, Carbonic.	$C^2N^2H^4O^3$, Allophanic acid.
$C^2H^2O^4$, Oxalic.	$C^3N^2H^4O^4$, Oxaluric acid. $C^3N^2H^2O^3$, Paraban.
$C^3H^2O^5$, Mesoxalic.	$C^4N^2H^4O^5$, Alloxanic acid. $C^4N^2H^2O^4$, Alloxan.

Similarly, among the diureides, some are formed from the corresponding monureides by elimination of one atom, and others by elimination of two atoms of water.

Mesoxalic acid, as already observed, is convertible, by deoxidation or hydrogenation, into tartronic acid, and by pushing the deoxidation a stage further, malonic acid is obtained, both of which acids are capable of forming monureides and diureides; and, in a similar manner, oxalic and carbonic acids furnish a variety of similar deoxidation-products.

Of the numerous compounds belonging to the uric acid group thus produced, the most important are included in the following table,* which is divided perpendicularly into three columns of an-ureides, mon-ureides, and di-ureides, and horizontally into three layers of carbonic, oxalic, and mesoxalic products. The compounds connected by dotted lines differ in composition from one another by an excess or deficit of one atom of urea minus one atom of water, while those standing on the same level in the adjoining columns, and unconnected by dotted lines, differ from one another by an excess or deficit of one atom of urea minus two atoms of water:—

An-ureides.	*Mon-ureides.*	*Di-ureides.*
CH^2O^3, Carbonic.	$C^2N^2H^4O^3$, Allophanic.	
	$C^3N^2H^6O^2$, Aceturea.	
	$C^3N^2H^6O^3$, Glycoluric.	$C^4N^4H^6O^2$, Glycoluril.
		$C^4N^4H^6O^3$, Allantoin.
$C^2H^4O^2$, Acetic.		
$C^2H^4O^3$, Glycollic.	$C^3N^2H^4O^2$, Hydantoin.	
$C^2H^4O^4$, Glyoxylic.	$C^3N^2H^4O^3$, Lantanuric.	$C^4N^4H^4O^2$, Mycomelic.
	$C^3N^2H^4O^4$, Oxaluric.	
$C^2H^2O^3$, Glyoxalic.		
$C^2H^2O^4$, Oxalic.	$C^3N^2H^2O^3$, Parabanic.	
		$C^5N^4H^4O$, Hypoxanthine.
$C^3H^4O^4$, Malonic.	$C^4N^2H^4O^3$, Barbituric.	$C^5N^4H^4O^2$, Xanthine.
$C^3H^4O^5$, Tartronic.	$C^4N^2H^4O^4$, Dialuric.	$C^5N^4H^4O^3$, Uric acid.
	$C^4N^2H^4O^5$, Alloxanic.	$C^5N^4H^6O^4$, Pseudo-uric.
$C^3H^2O^5$, Mesoxalic.	$C^4N^2H^2O^4$, Alloxan.	

Between some of the consecutive monureides shown in this table, there exist bodies formed by the union of the two consecutive monureides, with elimination of water. Such is the mode of formation of alliturie, lantanuric, and hydurilic acids, and of alloxantin; thus:

$$\underset{\text{Alliturie acid.}}{C^6N^4H^6O^4} = \underset{\text{Hydantoin.}}{C^3N^2H^4O^2} + \underset{\text{Lantanuric acid.}}{C^3N^2H^4O^3} - H^2O.$$

---

* Odling's "Lectures on Animal Chemistry" (London, 1866) p. 133.

$$\underset{\text{Leucoturic acid.}}{C^6N^4H^4O^5} = \underset{\text{Lantanuric acid.}}{C^3N^2H^4O^3} + \underset{\text{Parabanic acid.}}{C^3N^2H^2O^3} - H^2O.$$

$$\underset{\text{Hydurilic acid.}}{C^8N^4H^6O^6} = \underset{\text{Barbituric acid.}}{C^4N^2H^4O^3} + \underset{\text{Dialuric acid.}}{C^4N^2H^4O^4} - H^2O.$$

$$\underset{\text{Alloxantin.}}{C^8N^4H^4O^7} = \underset{\text{Dialuric acid.}}{C^4N^2H^4O^4} + \underset{\text{Alloxan.}}{C^4N^2H^2O^4} - H^2O.$$

All the compounds above formulated are described in their alphabetical places, except barbituric acid, glycoluril, glycoluric acid, and some derivatives of acetylurea or aceturcide.

1. *Oxalic Monureides.*—Glycoluric acid, $C^3N^2H^6O^3$, appears to be identical with Baeyer's hydantoic acid (iii. 177).

The barium-salt of this acid is produced, together with urea, by heating glycoluril (p. 961) with baryta-water:

$$\underset{\text{Glycoluril.}}{C^4N^4H^6O^2} + 2H^2O = \underset{\text{Glycoluric acid.}}{C^3N^2H^6O^3} + \underset{\text{Urea.}}{CN^2H^4O}.$$

The urea, however, splits up, in presence of the baryta, into carbonic acid and ammonia, so that carbonate of barium is deposited and ammonia given off.

The glycolurate of barium remains in solution, and by decomposing this solution with dilute sulphuric acid and evaporating the filtrate, glycoluric acid is obtained in transparent crystals. Its dilute solution, treated with silver-oxide in excess, yields an alkaline liquid, which gradually deposits a silver-salt, $C^3N^2H^5AgO^3$, in fine pearly scales and warty tufts of white needles; on acidulating with nitric acid, or adding nitrate of silver, the pearly scales are deposited immediately. (Rheineck, Ann. Ch. Pharm. cxxxiv. 219.)

Lantanuric acid, $C^3N^2H^4O^3$, is probably identical with the allanturic acid of Pelouze (i. 132), and with diffluan (ii. 322).

The relations of lantanuric and oxaluric acid to one another, and to another uric acid product called oxaluramide (iv. 277), are the same as those of hydrogen and water to ammonia:

H.H, hydrogen. . . . . $C^3N^2H^3(H)O^3$, lantanuric acid.
H.HO, water . . . . . $C^3N^2H^3(HO)O^3$, oxaluric acid.
H.H²N, ammonia . . . . $C^3N^2H^3(H^2N)O^3$, oxaluramide.

Tribromacetylurea, $C^3N^2H^3Br^3O^2 = CN^2H^3(C^2Br^3O)O$, is deposited from a solution of dibromobarbituric acid saturated with bromine, after standing for twelve hours, or more quickly on agitation, in colourless prismatic needles:

$$C^4N^2H^2Br^2O^3 + H^2O + Br = C^3N^2H^3Br^2O^3 + CO^2 + HBr.$$

The same compound is separated by chlorine from a solution of dibromobarbituric acid. It is sparingly soluble in cold water, easily soluble in alcohol; its vapour or powder strongly irritates the mucous membrane of the nose and eyes. It melts at 140°, without decomposition, to a colourless liquid, which solidifies at 123°; and when more strongly heated, gives off an oil (probably tribromacetamide), which solidifies on cooling, while cyanuric acid remains behind. Tribromacetylurea is decomposed by boiling with water, acids, or alkalis, yielding urea, carbonic acid, and bromoform, the formation of these products being, however, preceded by that of an intermediate acid, probably $C^3N^2H^3Br^3.H^2O$.—A solution of tribromacetylurea in ammonia becomes turbid immediately on boiling, with separation of bromoform; and the filtrate, when concentrated by evaporation, deposits long needles of isobiuret, $C^2N^3H^5O^2.H^2O$, which melts at 185° (biuret at 177°), but resembles biuret in other respects.

Monobromacetylurea, $C^3N^2H^5BrO^2 = CN^2H^3(C^2H^2BrO)O$, is obtained by mixing 3 pts. urea with 5 pts. bromide of bromacetyl, and recrystallising the product, from dilute alcohol, in needles, which dissolve sparingly in cold water, and are decomposed by water at the boiling heat, also by alkalis. Ammonia converts it into glycolylurea (hydantoin, iii. 177), or into oxacetylurea (glycoluric acid):

$$\underset{\text{Bromacetylurea.}}{CN^2H^3(C^2H^2BrO)O} = \underset{\text{Glycolylurea.}}{CN^2H^2(C^2H^2O)''O} + HBr.$$

$$\underset{\text{Bromacetylurea.}}{CN^2H^3(C^2H^2BrO)O} + H^2O = \underset{\text{Oxacetylurea.}}{CN^2H^3[C^2H^2(HO)O]O} + HBr.$$

2. *Oxalic Diureides.*—Allantoin and mycomelic acid are described in their alphabetical places.

Glycoluril, $C^4N^4H^6O^2$, is deposited in octahedral crystals, when a solution of allantoin, in about 30 pts. water, is acidulated with sulphuric acid, and treated with sodium-amalgam containing about 1 per cent. of sodium. It contains 1 at. oxygen less than allantoin. When boiled with baryta-water, it is resolved into glycoluric acid and urea (p. 960). (Rheineck.)

3. *Mesoxalic Monureides.*—The most important of these compounds appear to be alloxan and barbituric acid. **Alloxan**, the first discovered product of the artificial oxidation of uric acid, has recently been recognised by Liebig, as a pre-formed constituent of urine. When treated with bromine, it yields dibromobarbituric acid, convertible, by successive dehydrogenation, into bromobarbituric and **barbituric acid**, which last may be regarded as a sort of nucleus of the following series of compounds:

Mesoxalic Monureides.

$C^4N^2H^2(HO)^2O^3$ . . .	Alloxanic acid.
$C^4N^2H^2(Br^2)O^3$ . . .	Dibromobarbituric acid.
$C^4N^2H^4O^3$	Barbituric acid.
$C^4N^2H^3(Br)O^3$	Bromobarbituric acid.
$C^4N^2H^3(HO)O^3$ . . .	Dialuric acid.
$C^4N^2H^3(H^2N)O^3$ . . .	Uramile.
$C^4N^2H^3(H^2NSO^3)O^3$ . . .	Thionuric acid.
$C^4N^2H^3(NO)O^3$ . . .	Violuric acid.
$C^4N^2H^3(NO^2)O^3$ . . .	Dilituric acid.
$C^8N^4H^6(N^2O^5)O^6$ . . .	Violantin.

This last body, **violantin**, appears to be, not a residuary, but a completed compound of violuric and dilituric acids. The mutual relationship of barbituric acid, dialuric acid, and uramile in this subgroup, is strictly parallel to that of lantanuric acid, oxaluric acid, and oxaluramide in the oxalic group. Moreover, malonic and barbituric acids are homologous with oxalic and parabanic acids respectively.

Dibromobarbituric acid, or ***Bromalloxan***, $C^4N^2H^2Br^2O^3$. (Baeyer, Jahresb. 1863, p. 634; 1864, p. 632.)—This compound is produced by the action of bromine on violuric, dilituric, or hydurilic acid, according to the equations:—

$$\underset{\text{Violuric acid.}}{C^4N^2H^3(NO)O^3} + Br^4 = \underset{\text{Dibromobarbituric acid.}}{C^4N^2H^2Br^2O^3} + NOBr + HBr.$$

$$\underset{\text{Dilituric acid.}}{C^4N^2H^3(NO^2)O^3} + Br^4 = \underset{\text{Dibromobarbituric acid.}}{C^4N^2H^2Br^2O^3} + NO^2Br + HBr.$$

$$\underset{\text{Hydurilic acid.}}{C^8N^4H^6O^6} + H^2O + Br^6 = \underset{\text{Dibromobarbituric acid.}}{C^4N^2H^2Br^2O^3} + \underset{\text{Alloxan.}}{C^4N^2H^2O^4} + 4HBr.$$

To prepare it, hydurilic acid (iii. 220) is triturated to a paste with nitric acid; bromine is added as long as it is taken up, and the solution is warmed, whereupon it gives off nitrous acid, and deposits dibromobarbituric acid.

In this reaction the hydurilic acid is first converted into violuric or dilituric acid, which is then transformed into dibromobarbituric acid, as above.

This acid crystallises in colourless brilliant plates or prisms, belonging to the trimetric system. It is soluble in water, very soluble in hot alcohol and in ether. When boiled in aqueous solution, it is quickly decomposed into hydrobromic acid and alloxan; but it may be crystallised easily from nitric acid, which does not decompose it. It dissolves readily in alkalis, yielding compounds which are easily decomposed by heat, with loss of part of their bromine.

A solution of dibromobarbituric acid, digested with metallic *zinc*, loses half its bromine, and is converted into **bromobarbituric acid**, $C^4N^2H^3BrO^3$.

By *sulphydric acid*, in presence of water, it is reduced to dialuric acid:

$$\underset{\text{Dibromobarbituric acid.}}{C^4N^2H^2Br^2O^3} + H^2S + H^2O = \underset{\text{Dialuric acid.}}{C^4N^2H^4O^4} + 2HBr + S.$$

With a small quantity of *hydriodic acid*, it yields **hydurilic acid**:

$$\underset{\text{Dibromobarbituric acid.}}{2C^4N^2H^2Br^2O^3} + 6HI = \underset{\text{Hydurilic acid.}}{C^8N^4H^6O^6} + 4HBr + 3I^2;$$

but when it is heated with hydriodic acid in excess, the reduction proceeds a step further, and **barbituric acid** is produced:

$$\underset{\text{Dibromobarbituric acid.}}{C^4N^2H^2Br^2O^3} + 4HI = \underset{\text{Barbituric acid.}}{C^4N^2H^4O^3} + 2HBr + 2I^2.$$

A solution of dibromobarbituric acid, saturated with bromine, deposits crystals of tribromacetyl-urea (p. 960).

Barbituric acid, $C^4N^2H^4O^3.2H^2O$, crystallises in beautiful prisms, or sometimes in plates or needles, belonging to the trimetric system, sparingly soluble in cold, easily in hot water. By *fuming nitric acid*, it is converted into dilituric acid (ii. 965); by *potassic nitrate* into potassic violurate; and by *bromine*, into dibromobarbituric acid.—When boiled with caustic *potash*, it gives off ammonia, and yields malonate of potassium, $C^3H^2K^2O^4$, whence it appears to have the constitution of malonyl-urea:

$$CN^2H^2(C^3H^2O^2)''O \;=\; \underset{\text{Malonic acid.}}{C^3H^4O^4} + \underset{\text{Urea.}}{CN^2H^4O} - 2H^2O.$$

Barbituric acid is dibasic, and forms chiefly acid salts, which are obtained by treating the corresponding acetates with barbituric acid. The neutral lead-salt is obtained by precipitation with neutral lead-acetate. The following have been analysed:

Barbiturate of	Ammonium .	$C^4N^2H^3(NH^4)O^3$.
„	Potassium . .	$C^4N^2H^3KO^3$.
„	Sodium . .	$C^4N^2H^3K^2O^3.2H^2O$.
„	Barium . .	$C^8N^4H^6Ba''O^6.2H^2O$.
„	Copper . .	$C^8N^4H^6Cu''O^6.3H^2O$.
„	Lead. . .	$C^4N^2H^2Pb''O^3$.

Dibarbituric acid, $C^8N^4H^6O^5 = 2C^4N^2H^4O^3 - H^2O$.—The ammonium-salt of this acid is formed by heating barbituric acid with glycerin to 150°. The acid itself is separated by hydrochloric acid from its potassium-salt, as a white nearly insoluble powder. It is dibasic, and its acid salts are sparingly soluble in water, and mostly amorphous. The neutral dibarbiturates of alkali-metal are easily soluble in water, and are precipitated by alcohol.

Dibarbituric acid, treated with bromine and water, is transformed into yellow crystals of hydrobromate of dibromodibarbituric acid, $C^8N^4H^4Br^2O^5.HBr$, which, in contact with water or alcohol, are converted into white crystals of dibromodibarbituric acid, $C^8N^4H^4Br^2O^5$; this acid crystallises from hot water in large colourless crystals containing 1 at. water.

4. *Mesoxalic Diureides.*—The relationship between the three mesoxalic diureides—hypoxanthine, or sarcine, $C^5N^4H^4O$; xanthine, $C^5N^4H^4O^2$; and uric acid, $C^5N^4H^4O^3$—though long suspected, from the similarity of their formulæ, has but recently received an experimental demonstration at the hands of Strecker and Rheineck. These chemists have shown that hypoxanthine is converted into xanthine (*q.v.*) by oxidation with nitric acid, and, conversely, that uric acid, by deoxidation with sodium-amalgam, yields a mixture of xanthine and hypoxanthine. Xanthine is doubtless a monureide of barbituric and a diureide of malonic acid, in the same sense that uric acid is a monureide of dialuric, and a diureide of tartronic acid.

Pseudo-uric and uroxanic acids have the composition of hydrates of uric acid. Uroxanic acid, $C^5N^4H^{10}O^6 = C^5N^4H^4O^3.3H^2O$, is actually produced by the fixation of water on uric acid, its potassium-salt being formed by boiling uric acid for a long time in potash-ley. Pseudo-uric acid, $C^5N^4H^6O^4 = C^5N^4H^4O^3.H^2O$ (iv. 744), is not produced by direct oxidation of uric acid, but results from the combination of cyanic acid vapour with uramile or amidobarbituric acid, $C^4N^2H^3(H^2N)O^3$ (p. 961). For just as cyanic acid converts ammonia into anomalous cyanate of ammonia, or urea, so does it convert the residue of ammonia contained in uramile, into a residue of urea, thereby changing the amido-monureide into a simple diureide, thus:

$$\underset{\text{Uramile.}}{C^4N^2H^3(H^2N)O^3} + \underset{\text{Cyanic acid.}}{CNHO} \;=\; C^4N^2H^3(CN^2H^3O)O \text{ or } \underset{\text{Pseudo-uric acid.}}{C^5N^4H^6O^4}.$$

URINARY CALCULI.
URINARY PIGMENTS. } See the next article.
URINARY SEDIMENTS.

URINE. The secretion of the kidneys, the chief fluid excretion of man and of the higher animals. The healthy urine of man is a clear, yellowish, fluorescent liquid, of a peculiar odour, saline taste, and acid reaction, having a mean specific gravity of 1·020, and generally holding in suspension a little mucus.

Normal Constituents.—1. Water.—2. *Inorganic salts*: potassium, sodium, ammonia, calcium, magnesium, in combination with hydrochloric, phosphoric, sulphuric (nitric, carbonic) and silicic acids. The ash contains iron.—3. *Nitrogenous crystalline bodies*: urea, uric acid, hippuric acid, creatinine, xanthine (ammonia).—4. *Non-nitrogenous organic bodies*: sugar (in minute quantities, Brücke, Bence-Jones); lactic, succinic, oxalic, formic (malic), and phenylic acids. All these are found in small quantities; indeed, their normal occurrence can hardly be said to be certain.—5. *Free gases*: oxygen, nitrogen, carbonic acid. In 100 c.c. of urine, Planer found 0·87 N, 0·06 O, 4·54 free CO^2, 2·07 fixed CO^2, measured at 0° C., and 760 mm.

6. *Pigments.*—Several substances have been described, by various observers, as urinary pigments. Scherer (Ann. Ch. Pharm. lvii. 180), by decomposing, with hydrochloric acid and alcohol, the precipitates formed in urine by neutral and basic acetate of lead, obtained colouring bodies of variable composition. Harley (Wurt. Verdhl. v. 1) has given the name *urohæmatin* to a dark-red, amorphous, resinous substance, containing iron, readily soluble in alcohol, ether, fresh urine, and alkalis, but insoluble in water or acids, which he obtained from urine.—According to Thudichum (Brit. Med. Journ. Nov. 5, 1864), there is but one normal urinary pigment, *urochrome*, an amorphous substance, of a pure yellow colour, easily soluble in water, less so in ether, very dilute acids, and alkalis, and least of all in alcohol.—Schunk (Proc. Roy. Soc. xv. 1) believes that human urine contains two peculiar and distinct extractive matters (pigments), one soluble in alcohol and ether, of the composition $C^{68}H^{31}NO^{62}$; the other soluble in alcohol, but insoluble in ether, and of the composition $C^{38}H^{27}NO^{28}$: he regards the results of previous observers as being the products of greater or less decomposition.

In various diseases spontaneously occurring deposits of urates are often highly coloured of a red or rose-red hue. The pigments in such cases, known under the names of *rosacic acid*, *purpurin*, *uroerythrin*, have at present been little studied. The urine of man and of many animals (dog's urine contains a very large quantity) contains in health a small quantity, and in some cases of disease a very large amount, of a substance which was called by Heller *uroxanthin*, but which has been shown by Schunk to be *indican*. Fresh urine is precipitated with neutral and basic acetate of lead, the filtrate treated with ammonia, and the resulting precipitate washed, suspended in alcohol, and submitted to sulphuretted hydrogen. The filtered alcoholic solution is evaporated at a low temperature. It may be further purified by dilution with water, agitation with fresh hydrated oxide of copper, filtration, treatment with sulphuretted hydrogen, and renewed filtration. By the action of acids, indigo-blue and indigo-red, with which most probably the *uroglaucin* and *urorhodin* of Heller are respectively identical, may be obtained. The same change probably takes places through the natural decomposition of urine under certain conditions, for indigo-blue has been observed to occur spontaneously in urine on exposure to air. (Hassall.)

Harley regards all these matters as derivatives from his urohæmatin. Thudichum denies the existence of indican, and states that his urochrome yields, under various processes of decomposition, a black or brown powder, *uromelanin* (and a red resin), the latter consisting mainly of *uropittin*, insoluble, and *omicholic acid* (Scharling's omichmyl-oxide), soluble in ether,—and passes by a simple process, probably of oxidation, into uroerythrin. Hassall, however, was able to convert the blue pigment into isatin and aniline, and Schunk states that both the brown powder and resin are products from indican.

7. *Albuminoïd Matters and Ferments.*—If urine be mixed with four or five times its bulk of spirit, and a watery extract be made of the resulting deposit, a solution is obtained which is not precipitated by nitric acid, and which, on boiling, gives a precipitate of phosphates only, but, especially when concentrated by evaporation, shows the xanthoproteic and Millon's reactions very distinctly. The same solution rapidly converts starch into sugar. By treating urine with phosphate of calcium (see PEPSIN, SALIVA), ferments may be obtained capable of acting on starch, and of digesting albuminoïd matters.

8. *Extractives and other Matters.*—Colloïd acid of Marcet (Proc. Roy. Soc. xiv. 1). Decolorised urine is concentrated, treated with baryta, filtered, dialysed for 40 hours, again concentrated, and treated with basic acetate of lead, avoiding an excess. The lead-salt thus obtained may be decomposed with sulphuric acid. Schönbein is led to believe that urine normally contains a trace of peroxide of hydrogen. Urine is said to contain unoxidised sulphur and phosphorus.

Occasional or Abnormal Constituents.—*Blood*, the corpuscles being either entire and forming a sediment, or destroyed, and their hæmoglobin altered. *Pus*, *mucus*, *spermatic fluid*, &c. *Albumin*. In most instances the albumin of albuminous urine seems to be identical with serum-albumin. In some cases heat alone, in other cases nitric acid alone, fails to produce a precipitate. In a case of *Mollities ossium*, Bence-Jones found in the urine a peculiar protein-substance, which was coagulated by nitric acid in the cold, but redissolved on applying heat, reappearing, however, on cooling. *Fibrin* in bloody, and especially in the so-called "chylous" urine. *Casein*, or alkaline albuminates. *Fats*, *cholesterin*. *Leucine*, *tyrosine* (in certain hepatic diseases). *Allantoin* (in young children). *Cystine*, *xanthine*, *taurine*. *Glucose* (in diabetes and in smaller quantities in various chronic diseases). *Inosite*, *acetone*, *alkapton*, *lactic, acetic* (?), *metacetonic* (?), *butyric, valerianic* (?), *benzoic, succinic, oxalic, oxaluric, taurocholic, glycocholic, cholic acids. Biliary pigments, indigo-blue, melanin.*

These are products of metamorphosis; but the urine is also frequently the bearer of matters derived directly from the food. Of the substances which are capable of being absorbed from the alimentary canal into the blood, some reappear in the urine unchanged, while others are more or less altered, the changes being, with some exceptions, those of oxidation. Thus, there have been recovered from urine (in most instances, of course, in small quantities) arsenic, antimony, bismuth, copper, chromium, gold, iron, lithium, lead, mercury, silver, tin, zinc. The following substances also are said to pass unchanged:—alkaline carbonates, sulphates, nitrates, phosphates, borates, chlorates, silicates, chlorides, iodides, bromides; salts of calcium, magnesium, and barium; sulphocyanate and ferrocyanide of potassium; urea, leucine, hippuric acid, creatine, quinine (?), morphine, strychnine, atropine, alcohol (?), sulphovinates, sulphomethylates, sulphoamylates; gallic, pyrogallic, anisylic, cumaric, cuminic, camphoric, and piric acids, together with several pigmentary and odoriferous matters. The ammonia-salts pass unchanged, or are partially converted into nitrates. Free organic acids (oxalic, citric, &c.) are unchanged; their neutral salts, however, are converted into carbonates; malic acid, as malate of calcium, becomes succinic acid (Meissner). Sulphur and alkaline sulphides and sulphites are changed, in part at least, into sulphates. Sulphur taken in by the skin is said to give rise to xanthine. Free iodine becomes alkaline iodide. Tannic is changed into gallic acid. Benzoic acid, hydride of benzoyl, cinnamic acid, quinic acid, and mandelic acid give rise to hippuric acid. Nitrobenzoic acid is converted into nitrohippuric acid, chlorbenzoic into chlorhippuric, salicylic into salicyluric, toluic into toluric, anisic into anisuric acid. Uric acid, allantoin, alloxantin, guanine, glycocine, theine, and theobromine are said to give rise to an increase of urea. Salicin is converted into salicylol, salicylic acid (salicyluric), and saligenin. Ferrocyanide of potassium becomes ferricyanide. Indigo-blue is said to be reduced to indigo-white.

Acidity of Urine.—Healthy urine has generally when passed an acid reaction; the mean amount of acidity may be taken as equivalent to 2 grms. of oxalic acid in the 24 hours. The degree of acidity varies from time to time; it is lessened during digestion; indeed the urine may, after a meal, become alkaline. The acidity is due, in part at least, to the acid phosphate of sodium, but the quantity of that salt present in healthy urine is insufficient to account for the whole of the acidity; the rest is supplied by some free acid or acids—hippuric, lactic, colloïd. According to Scherer, the acidity of urine exposed to the atmosphere gradually increases for several days, through an "acid fermentation," in which the mucus and the pigmentary and extractive matters take part; afterwards a species of yeast appears. This increase of acidity is, however, denied by Bence-Jones.

Alkaline Urine.—Sooner or later, within a few days, or not until two or three weeks, the acid gives way to an alkaline reaction, the urea becoming converted into carbonate of ammonia through a process of fermentation. This change is accompanied by the appearance of crystals of triple phosphate, confervoïd growths, and vibriones. It may take place almost immediately after the urine has been passed, or (in certain diseases) even within the bladder. The mucus has been supposed to act as a ferment; but this is probably incorrect. It is much more likely that the change is due to the action of a distinct ferment, perhaps an organic being.

Table (after **Parkes***) of the Amounts of the several Urinary Constituents passed in Twenty-four Hours.*

	By an average man of 66 kilos.		Per 1 kilo. of body-weight.	
Water	1501·00	centimetres.	23·000	centimetres.
Total solids	61·14	grammes.	·93	grammes.
Urea	33·18		·500	
Uric acid	·555		·0084	
Hippuric acid (Bence-Jones)	·4		·006	
Creatinine (Neubauer)	·91		·014	
Pigment and extractives	10·00		·151	
Sulphuric acid	2·012		.0305	
Phosphoric acid	3·164		·048	
Chlorine	(8·21) 7·00		·126	
Ammonia	·77			
Potassium	2·5			
Sodium	11·09			
Calcium	·260			
Magnesium	·207			
Iron				

Urine, being the vehicle through which the body gets rid of by far the greater part of the solid matters resulting from or concerned in the vital processes of metamorphosis, naturally varies within the widest limits, as to both the absolute and relative quantities of its constituents, according to the condition, behaviour, and treatment of the organism. The amount of urea passed during a given time is, taken relatively to the body-weight, increased in childhood and lessened in old age; it is directly dependent on the quantity and quality of food consumed, and is obscurely connected with the labours of the frame (see NUTRITION, iv. 153). The uric acid is increased by food (especially by animal food), by exercise, by hindrances to the action of the skin, or to the function of respiration in general, and by various morbid conditions. Hippuric acid is increased by vegetable food; in the horse it is said to be increased by work. Creatinine is increased by animal food. The chlorides, sulphates, and phosphates vary with the food; the sulphates and phosphates are said to run, to some extent, parallel with the urea, and to be increased by muscular work, and the phosphates (especially the earthy phosphates) by mental labour. For further details consult Parkes, "The Composition of the Urine in Health and Disease."

Urine of other Animals.—The urine of carnivora in general is acid and clear, contains a large amount of urea, but only a small quantity of uric acid. That of herbivora is alkaline and turbid (from carbonates), contains hippuric but no uric acid (unless the animals are starving or feeding on flesh), a large quantity of earthy carbonates, and but little phosphates. The urine of the dog is wholly or very nearly free from uric acid; contains cynurenic acid, hippuric acid, a large quantity of indican; and, when the animal is feeding on flesh and fat, some succinic acid. That of the horse is rich in hippuric acid and earthy carbonates, and contains a decided quantity of sugar. That of the cow contains from ·4—2·7 per cent. of hippuric acid (Henneberg); from it have been obtained damolic, damaluric, and taurylic acids. The urine of the sucking calf is remarkable for the presence of allantoin and the absence of hippuric acid, a feature which disappears on weaning. The urine of the pig is alkaline, and rich in alkaline carbonates, clear even on standing for some time, but becomes turbid when heated, contains urea, but neither uric nor hippuric acid. The portion of the excrement of birds that corresponds to urine is rich in uric acid and urates of ammonia and lime. Urea is said to exist in the excrement of carnivorous birds. The urine of ophidians consists of uric acid, urates of sodium, potassium, and ammonium, some urea, and a little calcic phosphate. The urine of the *Testudo tabulata* contains urea, uric and hippuric acids, chlorides, sulphates, and a small quantity of phosphates. The urine of the frog contains urea, chlorides, and phosphates. Uric acid has been found in the excrement of butterflies, beetles, caterpillars, and snails, and guanine in the excrement of spiders, and in certain organs of mollusca.

Urinary Sediments.—Many specimens of urine exhibit, on standing, deposits or sediments consisting of morphological elements, and of chemical bodies, crystalline or amorphous. To the first class belong blood-corpuscles, pus- and mucus-corpuscles, spermatozoa, epithelial scales, casts of the uriniferous tubes, &c. The members of the second class are various and many.—*Urates* (the ordinary brick-dust sediment) in amorphous irregular particles, round globules, and fine acicular crystals, consisting of a great excess (82 per cent.) of uric acid in combination with variable quantities of ammonia, soda, potash, and lime.—*Uric acid*, in crystals of various shapes, mostly coloured, chiefly rhombic prisms and plates, sometimes thin hexagonal plates, dumb-bells (artificial only?).—*Phosphates*: ammonio-phosphate of magnesium, in large, transparent, rhombic prisms, or penniform; phosphate of calcium, amorphous, or crystallising in very various shapes, often forming glomerules or rosettes, with lozenge-shaped or acicular elements, sometimes penniform.—*Oxalate of calcium*, in octahedral crystals, or forming the "dumb-bell" bodies.—*Carbonate of calcium* occasionally occurs in man, sometimes in the form of dumb-bells. It is very abundant in the urine of the horse, in peculiar globular bodies, formed of concentric layers.—*Hippuric acid* (uncommon), in acuminated needles or acicular crystals.—*Cystine*, amorphous, or in transparent, colourless, hexagonal plates.—*Leucine*, in peculiar round bodies, having a concentric arrangement, or in needles, or granular.—*Tyrosine*, in acicular heaps and rosettes.—*Xanthine*, amorphous, or in small oblong plates (Bence-Jones).—*Cholesterin.*—*Sulphate of calcium*, in acicular crystals, has been observed. (Valentiner.)

Urinary Calculi.—In the pelvis of the kidney, in the ureters, in the bladder, and in the urethra are found concretions of very variable size, form, consistency, structure, and composition. They are called *urinary* (*renal*, *ureteric*, *vesical*, *urethral*) *calculi*, and are made up chiefly of the solid constituents of the urine. Sometimes homogeneous, they are more frequently formed of numerous concentric layers. A central portion, the *nucleus*, may generally be distinguished from the external portions, and is sometimes formed by a foreign body.

Uric acid, urates of ammonium, calcium, potassium, sodium, and magnesium, phosphates of calcium, of ammonium and magnesium, and of iron, carbonates of calcium and magnesium, oxalates of calcium and ammonium, hippurate of ammonium, chloride of ammonium, cystine, xanthine, ferric oxide, silica, mucus, fat, blood, colouring and other extractive matters, have all been mentioned as constituents of urinary calculi. It is very unusual to meet with calculi formed exclusively of a single substance; many calculi are formed chiefly of uric acid, others chiefly of oxalate of calcium, but these generally contain at least a small quantity of other matters. The most common forms are uric acid with urates of ammonium or calcium, ammonio-magnesian phosphate with phosphate and carbonate of calcium, uric acid with phosphates, oxalate of calcium with phosphates. The concentric layers are frequently distinct, not in appearance only, but also in composition; and a curious alternation of material is at times observed, uric acid, for instance, changing place with urates, phosphates, oxalates, &c. A nucleus of uric acid is frequently surrounded by an external coat of phosphates, but a nucleus of phosphates with a coating of uric acid, &c., is never observed. The most external layers in many calculi of various composition is apt to be phosphatic. The oxalate calculi (often called *mulberry*, from their peculiar form) are generally the hardest, the phosphatic the softest. Calculi of cystine are rare, those of xanthine still more so.

The following may be taken as analyses of the more typical forms:

Uric acid.

Uric acid	92·8	84·69
Urates	3·2	9·03
Ammonio-magnesian phosphate		1·12
Extractives	1·00	2·61
Water	3·00	

Phosphatic.

Urate of sodium . . .	9·77
Calcic phosphate . . .	34·74
Ammonio-magnesian phosphate	38·35
Calcic carbonate . . .	3·14
Magnesic carbonate . .	2·55
Extractives, &c. . . .	6·87

Oxalate.

Calcic oxalate . .	63·5
Calcic phosphate . .	6·2
Water and organic matters	30·3

Analysis of Urine.

Determination of Urea. (Liebig's method.) *Prepared urine* (if albumin be present it must be separated by boiling; some urea will probably be lost): two volumes of urine are mixed with 1 volume of a "baryta mixture" (consisting of 2 volumes of baryta-water to 1 volume of a solution of barium-nitrate, both saturated in the cold), and filtered.—*Urea-solution*: 2 grms. of pure urea are dissolved in water, and the solution diluted to 100 c.c.—*Mercurial solution*: a concentrated solution of pure mercuric nitrate is diluted with four times its bulk of water. 10 c.c. of the urea-solution are measured into a beaker, and the mercurial solution is slowly added from a burette as long as any precipitation takes place; a drop of the mixture is then let fall by a glass rod into a drop of a solution of sodic carbonate, placed in a watch-glass, or on a glass plate, over some black surface. If the precipitate, which occurs on the mingling of the two drops, does not become in a few seconds distinctly yellow, more of the mercurial solution must be added to the mixture in the beaker, and the trial made again. As soon as a distinct yellow colour appears (the shade being noticed by the observer in order to guide him afterwards), the trial drops are returned into the beaker, and a little of the soda-solution added, until the mixture is only faintly acid. A drop is then again to be tried with the soda-solution; and if the yellow colour does not show itself, a small quantity of the mercurial solution must still be added to the mixture in the beaker, and trial made again. When the yellow colour has been thus obtained, the total quantity of mercurial solution used is read off; it corresponds to ·2 grm. urea. The mercurial solution itself is then diluted according to these results, so that 20 c.c. of it corresponds to 10 grms. of the urea-solution, *i.e.* so that 10 c.c. correspond to ·1 grm. urea. It is well not to add, at once, the whole of the water required; but to stop a little short of that, and titrate again, since, practically, the degree of dilution required is rather less than that suggested by calculation.

Method.—Of the prepared urine, 15 c.c., corresponding to 10 c.c. of the original urine, are poured out into a beaker or flask, and the mercurial solution is added until the yellow reaction, as described above, is obtained; the mixture is also in the same way reduced in acidity, and trial made again. The quantity of mercurial solution used will give the amount of urea in the 10 c.c. of urine. Unfortunately, the reaction is exact only for fluids containing 2 per cent. of urea; its appearance is premature when more, and is delayed when less than that percentage is present. If the prepared urine contains an excess of urea, double its volume of the mercurial solution will have been used, and yet no reaction set in. Hence, if, on arriving at this point, 1 c.c. of distilled water be added to the mixture for every additional 2 c.c. of the mercurial solution employed, the proportion of urea will be maintained at 2 per cent., and the final result will be correct. Thus if, after the addition of 30 c.c. of the mercurial solution to 15 c.c. of prepared urine, the reaction is not seen, 1 c.c. of distilled water is added, and the process continued. Supposing the reaction finally sets in when 10 c.c. more, or 40 c.c. in all, of the mercurial solution have been used, the 5 c.c. of distilled water, which have been also added, will bring up the original 15 c.c. of urine to 20 c.c.; the 40 c.c. of mercurial solution will have been employed on a fluid containing 2 per cent. of urea. If the prepared urine contains less than 2 per cent. of urea, an approximate correction may be made by subtracting ·1 c.c. from every 5 c.c. of the mercurial solution that is run short of the normal 30 c.c. Thus, if with 15 c.c. of prepared urine, the yellow colour is struck on using 20 c.c. of the mercurial solution, ·2 c.c. $(30-20=5\times 2)$ are deducted, and therefore 19·8 c.c. taken as the correct result. A further correction must be made for chloride of sodium, the presence of which delays the reaction. We may make an approximate correction by deducting from the quantity of mercurial solution employed 1·5 c.c.—2·5 c.c., according to the quantity of chloride of sodium present. Or we may first remove the chloride. To 15 c.c. of prepared urine, one or two drops of solution of neutral chromate of potash are added, and a solution of nitrate of silver dropped in from a burette, until the appearance of the red chromate of silver indicates that the whole of the chloride has been thrown down; the mercurial solution can then be at once used without removing the silver-precipitate. The reduction in the percentage of urea, by the addition of the silver-solution, must of course be taken into account. Or two portions of prepared urine may be taken of 15 c.c. each. One is neutralised with nitric acid, the mercurial solution added, and the point marked at which a permanent precipitate (a distinct cloud, not a mere opalescence) is produced. The other is titrated in the usual way. The number of c.c. employed in the latter, minus those employed in the former operation, will give the real quantity of urea. It must be remembered that other nitrogenous bodies, creatinine, allantoin, &c., are precipitated by the mercurial solution in the same way as urea.

Heintz and Ragsky's Method.—A given quantity (20 c.c.) of urine is precipitated with tetrachloride of platinum, and the precipitate washed with spirit, dried, and weighed. From 2 to 5 c.c. of the same urine (according to concentration) are heated to 180°—200°, in a covered platinum or porcelain capsule, with an equal bulk of sulphuric acid; and after cooling are diluted with water, filtered, and precipitated with tetrachloride of platinum. Both precipitates are calculated for 100 c.c. urine, and the former deducted from the latter; the result multiplied by ·13423 gives the percentage of urea.

Davey's Method.—A small quantity of urine is poured into a graduated glass tube a third full of mercury; the tube is then filled with a solution of sodic hypochlorite, rapidly inverted over a saturated solution of chloride of sodium, and left to stand several hours. The quantity of gas (nitrogen) given out is read off. 1·549 cubic inches of nitrogen at 60° F. and 30″ bar. = 1 grain urea.

Uric acid, ammonia, &c. are in this method confounded with urea.

Bunsen's Method.—A given quantity of prepared urine is heated, at 220°—240°, with chloride of barium in a sealed tube, and the resulting carbonate of barium determined. 1 grm. barium-carbonate = ·4041 urea.

Uric Acid.—To 200 c.c. of urine, 10 c.c. of hydrochloric acid are added, the mixture allowed to stand 48 hours in a cool place, filtered through a very small filter, on which the crystals are placed, washed, dried, and weighed. The wash-water should not exceed 30 c.c.; if the last drops still produce cloudiness in a silver-solution, more must of course be used; and for every *additional* cubic centimetre of wash-water used, ·045 milligramme is added to the amount of uric acid found. This correction is a compromise between the loss arising from the partial solubility of the uric acid, and the gain due to the colouring-matter inseparably connected with the crystals. Hassall (Lancet, 1867, May 6), has shown that the mixture of uric acid and pigment, which is usually weighed as uric acid, varies extremely, according to the concentration of the urine, the amount of acid employed, the time allowed for crystallisation, and the surrounding temperature. If the urine contains albumin, this must first be removed by coagulation, with the very careful use of dilute acetic acid, using afterwards strong acetic, instead of hydrochloric, acid to precipitate the uric acid.

Hippuric Acid.—The urine is digested with animal charcoal (2 grammes to each 10 c.c.), and filtered; 200 c.c. are evaporated down to 50 c.c., 20 c.c. of hydrochloric acid added, and the mixture allowed to stand for twenty-four hours in a cool place. The hippuric acid which crystallises out is collected on a weighed filter, washed with a small quantity of cold water until the filtrate is colourless, dried at 100°, and weighed. The wash-water is collected and measured, and for every 6 c.c. of it, ·01 gramme is added to the weight of hippuric acid, in order to correct the error due to that substance being slightly soluble in cold water. This process is of course useless where uric acid is present.

Creatinine.—To 300 c.c. of urine, rendered alkaline with milk of lime, a solution of calcic chloride is added as long as any precipitate occurs. The mixture is allowed to stand for one or two hours, and filtered. The filtrate and washings are evaporated to dryness in a water-bath, and, while still warm, treated with 30 or 40 c.c. of alcohol, 95 per cent. The mixture, after standing for four or five hours in a cool place, is passed through a small filter, and the filter washed with small quantities of spirit.

The filtrate and washings—reduced in bulk, if necessary, to 40 or 50 c.c. by being placed over hot plates—are mixed with 5 c.c. of a solution of chloride of zinc (specific gravity 1·2, absolutely free from acidity), and allowed to stand for three or four days in a very cool place. The crystals that appear are collected on a small filter, washed first with the mother-liquor, and then with small quantities of spirit, dried at 100°, and weighed. 100 pts. of zinc-compound = 62·44 pts. of creatinine.

Albumin.—From 30 to 100 c.c. of urine, according to concentration, are heated with the naked flame, a drop or two of acetic acid being added, until the albumin is thoroughly coagulated, and the fluid capable of being filtered. The deposit is dried at 120°, and over sulphuric acid, until it ceases to lose weight. Other matters are carried down with the albumin, but these are insignificant.

Sugar.—In diabetes, when the quantity of sugar is very considerable, the determination may be made with the alkaline copper-solution, by the saccharimeter, or by fermentation. When the quantity of sugar is very small, the following process may be adopted:—A given quantity of urine (1000 cubic centimetres) is concentrated, and precipitated with sugar of lead and filtered; the filtrate is precipitated with acetate of lead and filtered. This second filtrate is precipitated with ammonia, the deposit suspended in alcohol, submitted to sulphydric acid, and filtered. The spirit filtrate is evaporated, and its sugar determined in any of the usual ways.

Chlorides.—In fresh urine, free from albumin, much uric acid, or mucus, the chlorides may be determined with tolerable accuracy by the silver and chromate of potash method.

Phosphates may be determined by the uranic oxide process.

Ammonia.—Twenty cubic centimetres of urine are placed in a shallow vessel, over which is arranged another small shallow vessel containing 10 c.c. of a standard solution of dilute sulphuric acid; and the whole is covered with an airtight bell-jar. The bell-jar is slightly raised, 10 c.c. of milk of lime quickly introduced into the urine, and the jar at once replaced. In about 48 hours, the whole of the ammonia is disengaged from the urine, and absorbed by the sulphuric acid. By titrating the sulphuric acid after the experiment, and comparing it with the standard solution, the amount of ammonia is arrived at.

Bile Acids.—Urine is precipitated with basic acetate of lead and a little ammonia; the precipitate is washed, boiled in alcohol, and filtered hot; the alcoholic solution is treated with a few drops of soda, and evaporated to dryness; the residue extracted with absolute alcohol; the filtered solution reduced in volume, mixed with an excess of ether, and left to crystallise. The crystalline deposit is mixed with dilute sulphuric acid (1 to 4), and a few drops of a solution of cane-sugar added. The mixture, on being gently warmed, should give the purple coloration of Pettenkofer. M. F.

URINE, FUSIBLE SALT OF. *Sal urinæ fusibilis.*—Ammonio-sodic phosphate.

URINE, SPIRIT OF. The solution of ammonium-carbonate, obtained by distilling putrid urine.

UROCHROME, UROCYANIN, UROERYTHRIN, UROGLAUCIN, UROHÆMATIN, UROMELANIN, UROPITTIN, URORHODIN. See URINARY PIGMENTS (p. 963).

UROSTEALITE (from *οὖρον*, urine; *στέαρ*, tallow; and *λίθος*, stone).—A fatty substance found in a urinary calculus. On evaporating the solution of the calculus in carbonate of sodium, adding a little sulphuric acid, extracting with ether, and leaving the ether to evaporate, the urostealite was obtained as a violet residue, which softened in boiling water without dissolving, was sparingly soluble in alcohol, more easily in ether and in caustic potash, less easily in ammonia and in carbonate of potassium. It softened when heated, and when more strongly heated gave off a thick smoke, and an odour like that of benzoin and shellac. (Heller, Arch. f. Phys. u. pathol. Chemie, u. Mikros. 1845, p. 1.)

UROXANIC ACID. $C^5N^4H^{10}O^6$. (Städeler, Ann. Ch. Pharm. lxxviii. 286; lxxx. 119.)—A product obtained by boiling uric acid with rather strong potash-ley:

$$\underset{\text{Uric acid.}}{C^5N^4H^4O^3} + 3H^2O = \underset{\text{Uroxanic acid.}}{C^5N^4H^{10}O^6}.$$

Other products are formed at the same time—namely, lantanuric acid, urea, formic acid, and oxalic acid.

On leaving the resulting solution in contact with the air, it absorbs carbonic acid, and slowly deposits acid urate of potassium in the form of a white powder; but, after several weeks or months, tabular crystals of potassic uroxanate are formed, the urate disappearing at the same time. By decomposing the solution of the uroxanate with hydrochloric or sulphuric acid, the uroxanic acid is obtained in indistinct prismatic crystals, or from warm moderately dilute solutions, in colourless transparent tetrahedrons.

Uroxanic acid is slightly soluble in cold water, quite insoluble in cold alcohol. It is easily decomposed even by boiling with water, giving off carbonic anhydride. The dry acid heated in a glass tube above 100°, gives off water and carbonic anhydride. If, however, the temperature be maintained at 130° till the weight of the residue becomes constant, the acid is found to have lost 34·8 per cent. of its weight, and a yellowish hygroscopic substance is left, called uroxil by Städeler, and having the composition of uroxanic anhydride, $C^5N^4H^8O^5$ (which is also that of dialurate of ammonium). At a stronger heat, uroxanic acid melts to a brown liquid, gives off ammonia, and probably also cyanide of ammonium, yields an oily distillate solidifying as it cools, and leaves a small quantity of carbonaceous residue. Strong nitric acid does not act on uroxanic acid in the cold, but dissolves it when heated, without evolution of gas, the solution on cooling yielding crystals, probably a product of oxidation. The mother-liquor yields, on evaporation, a white residue, which is not coloured by carbonate of ammonium.

Uroxanic acid is dibasic, the general formula of its salts being $C^5N^4H^8M^2O^5$. Some of the uroxanates are soluble in water, but most of them are insoluble in alcohol.

The *ammonium-salt* separates, in small four-sided tablets, on adding alcohol to a solution of the acid in dilute ammonia.—The *potassium-salt*, $C^5N^4H^8K^2O^5.3H^2O$, obtained as above described from uric acid, crystallises in large, nacreous, four-sided plates, with angles of 97° and 83°. It is moderately soluble in cold, very soluble in hot water, insoluble in alcohol; gives off its water of crystallisation at 100°; and at a higher temperature melts, gives off a little carbonate of ammonium, and leaves a residue blackened by charcoal.

The *barium-salt* separates, on mixing a solution of the acid in excess of ammonia with chloride of barium, and adding alcohol, in thick flocks which gradually change to slender shining needles.—The *calcium-salt*, obtained in like manner, forms small, shining, four-sided plates, which, by boiling in the liquid, are converted into larger crystals, like those of the barium-salt.—The *lead-salt*, $2C^5N^4H^8Pb''O^5.H^2O$, is precipitated by nitrate of lead from the solution of the potassium-salt, in delicate satiny scales, quite insoluble in water, and becoming anhydrous at 100°.—The *silver-salt* is obtained in like manner, as a white flocculent precipitate, but soon settles down to a dense powder, which turns red on exposure to light, and black when heated in the liquid.

UROXANIC ANHYDRIDE. See preceding article.

UROXANTHIN. See Urinary Pigments (p. 963).

UROXIL. Syn. with Uroxanic Anhydride.

UROXIN. Syn. with Alloxantin (i. 138).

UROXYL. Syn. with Uroxil.

URSONE. $C^{10}H^{16}O$?—A resinous body obtained from the leaves of the red bearberry, *Arctostaphylos uva-ursi*. It was first prepared by Trommsdorff in 1854 (Arch. Pharm. [2], lxxx. 273), and further examined by Hlasiwetz (J. pr. Chem. lxiv. 123), who assigned to it the formula $C^{20}H^{17}O^2$. To prepare it, the leaves of the bearberry, after being freed from arbutin by exhaustion with water, are treated with alcohol, the solution is evaporated, the residue treated with water and ether, and the ursone which then remains undissolved, is purified by crystallisation from alcohol. Or the leaves are treated with ether in a displacement apparatus, whereby a dark-green extract is obtained, which deposits a considerable quantity of crystalline ursone to be purified by crystallisation from alcohol.

Ursone crystallises in slender colourless needles, having a silky lustre, tasteless and inodorous, insoluble in water and in aqueous acids or alkalis, soluble with difficulty in ether or alcohol. It melts at 190°—200°, and solidifies again in the crystalline form on cooling; if heated above its melting-point, it remains amorphous after cooling, and at a still higher temperature boils, and appears to volatilise without decomposition.

According to Hlasiwetz, ursone agrees in composition and in most of its properties with hartin from lignite (iii. 14).

URTICA. The stinging power of nettles, *Urtica urens* and *U. dioica*, is due (according to Saladin) to acid carbonate of ammonium, contained in glands beneath their epidermis; the juice contains nitrate of potassium and nitrate of calcium. According to Bollig, water distilled over the herb contains carbonate of ammonium; according to Gorup-Besanez, it contains formic acid.

The yellowish decoction of the leaves, when left to dry in contact with the air, especially in presence of alkalis, is said, by Leuch, to yield a fine emerald-green colour. The herb of *U. urens* yields, by fermentation, a so-called ferment-oil (ii. 636) (Bley). The seeds of both kinds of nettle are said to be useful as remedies in cases of dysentery.

The fibre of many species of *Urtica* yields useful tissues. The Chinese are said to fabricate a fine silky stuff from the fibres of *Urtica nivea*. (Handw. d. Chem. ix. 68.)

USNIC ACID, or **USNIN.** An acid obtained from several species of lichen. It was first prepared and examined by Knop (Ann. Ch. Pharm. xlix. 103), and further investigated by Rochleder and Heldt (*ibid.* xlviii. 12), Thomson (*ibid.* liii. 252), Stenhouse (*ibid.* lxviii. 97, 114), and Hesse (*ibid.* cxvii. 343).—Stenhouse assigned to it the formula $C^{38}H^{17}O^{14}$—more probably $C^{38}H^{16}O^{14}$, or $C^{19}H^{16}O^{7}$; according to Hesse, it is $C^{18}H^{18}O^{7}$. It is found in *Usnea florida*, *U. harta*, *U. plicata*, *U. barbata*, *Ramalina calicaris*, *Cladonia rangiferina*, *Parmelia furfuracea*, *Evernia prunastri*, and others.

According to Stenhouse, the several species of *Usnea* are best adapted for the preparation of usnic acid, especially *Usnea florida*; next in point of eligibility comes *Cladonia rangiferina*, while the several species of *Ramalina* and *Evernia prunastri* are less adapted for the purpose, because they yield resinous acids difficult to purify. Hesse uses *Ramalina calicaris* (var. *fraxinea* and *chnaumatica*) for the preparation of alpha-usnic acid, and *Cladonia rangiferina* for the preparation of beta-usnic acid.

Preparation.—Knop exhausts the lichens with ether in a displacement apparatus, then distils off the ether, and treats the residue with alcohol; the alcoholic solution thus obtained deposits usnic acid in crystals on cooling. Rochleder and Heldt digest the lichens with a mixture of ammonia and aqueous alcohol, filter the liquid after some minutes, then mix it with one-third of its volume of water, and neutralise with acetic acid; the usnic acid thereby precipitated is washed, and recrystallised from alcohol.—Stenhouse exhausts the lichens with milk of lime, and precipitates with hydrochloric acid.

Hesse also exhausts the lichens (*Ramalina calicaris*, var. *fraxinea* and *chnaumatica*) with milk of lime, supersaturates with hydrochloric acid, and boils for a short time, whereupon alpha-usnic acid crystallises out. The deposit is washed with water, then boiled with alcohol, and the residue is dissolved in boiling acetic acid, the solution mixed with animal charcoal, and filtered.—To prepare beta-usnic acid from *Cladonia rangiferina*, Hesse exhausts the lichen with dilute soda-ley; saturates with hydrochloric acid; washes the precipitate, which contains brown humous substances, with water; dries it, and exhausts it with ether; evaporates the ethereal solution; and mixes the residue with alcohol. Beta-usnic acid then crystallises out, and may be purified by recrystallisation from alcohol with addition of animal charcoal.

Properties.—Usnic acid forms thin, light, sulphur-yellow needles, which become strongly electric by friction, are not moistened by water, dissolve but sparingly in ordinary alcohol, even at the boiling heat, but easily in boiling ether or turpentine-oil.

Usnic acid melts when somewhat strongly heated, alpha-usnic acid at 203° (Hesse), at 200° (Knop); beta-usnic acid at 175°: this difference of melting-point is the only essential distinction between the two acids. Melted usnic acid is yellowish and resinous, and solidifies in the crystalline form on cooling; at a higher temperature it yields a crystalline sublimate, an oily distillate containing beta-orcein, and a carbonaceous residue. Usnic acid is not coloured by ferric chloride or by hypochlorite of sodium.

Chlorine converts usnic acid into a resinous body; *sulphuric acid* dissolves it, forming a yellow solution, which is precipitated by water. *Nitric acid* heated with it, forms a yellow resin. Usnic acid dissolves easily in *alkaline liquids*: the solutions, which contain beta-orcein together with a resin, become dark-red on exposure to the air, and at last nearly black.

Usnic acid is monobasic, the composition of its salts being $C^{18}H^{17}MO^{7}$, according to Hesse; $C^{19}H^{15}MO^{7}$, according to Knop. The usnates of the alkali-metals are soluble in water; the rest are insoluble in water, but soluble in alcohol; ether extracts usnic acid from them.

Usnate of ammonium, obtained by passing ammonia-gas into absolute alcohol in which usnic acid is suspended, forms needle-shaped crystals.—The *potassium-salt*, $C^{18}H^{17}KO^{7}.6H^{2}O$, is prepared by boiling usnic acid with a strong solution of potassic carbonate. It separates almost completely from the solution on cooling, and when recrystallised from alcohol, forms white laminæ, which give off all their water at 130°. Its solution froths like soap-water, and, when mixed with a large quantity of water. deposits an acid salt.—The *sodium-salt* forms stellate groups of silky needles; it reacts like the potassium-salt, but is more easily decomposed.—The *barium-salt*, $C^{36}H^{34}Ba''O^{14}$, may be crystallised from alcohol; the aqueous solution quickly becomes coloured on exposure to the air.—The *cupric salt*, $C^{36}H^{34}Cu''O^{14}$, is a green precipitate; the *lead-salt*, a white precipitate; the *silver-salt*, a white precipitate which quickly blackens.

UVITIC and **UVITONIC ACIDS.** Acids produced, according to Finck, by the action of baryta-water on pyroracemic acid. The former has the composition $C^{9}H^{8}O^{4}$; the latter appears to be merely a syrupy modification of pyroracemic acid (iv. 770).

UWAROWITE, *Chrome-garnet*, *Chrome-lime-garnet*, $3CaO.Cr^{2}O^{3}.3SiO^{2}$, with small quantities of alumina, ferrous oxide, and magnesia, occurs at Saranowskaja, near Bissersk, and near Kyschtimsk, in the Ural, in rhombic dodecahedrons, and massive, with imperfectly conchoïdal or splintery fracture, emerald-green colour, and greenish-white streak, vitreous lustre, more or less transparent on the edges. Hardness = 7·5 to 8·0. Specific gravity = 3·4 to 3·5. It does not fuse by itself before the blowpipe, but forms a clear olive-green glass with borax. (See GARNET, ii. 772.)

V

VACCINIC ACID. This name was given by Lerch (Ann. Ch. Pharm. xlix. 227) to a volatile acid, obtained on one occasion by the saponification of butter from cow's milk, but which appears to have been merely a mixture of butyric and cupric acids.

VACCINIUM. A small genus of plants including the bilberry and whortleberry. The green parts of the common bilberry (*Vaccinium Myrtillus*) contain quinic acid (Zwenger, Ann. Ch. Pharm. cxv. 108). The fruit contains, according to Fresenius (*ibid.* ci. 225):

Fruit-sugar	5·8	Soluble in water.
Free acid (regarded as malic acid)	1·3	
Albuminous substances	0·8	
Pectin, gum, colouring-matter	0·5	
Ash	0·8	
Kernel and husk	12·8	Insoluble in water.
Pectose	0·2	
Ash	0·55	
Water	77·5	

The colouring-matter of the berries forms with lead-oxide, a fine blue compound which is coloured green by alkalis. The berries yield, by fermentation, a kind of brandy ("Heidelbeerbrantwein" or "Heidelbeergeist") which is prepared in large quantities in many parts of the Black Forest.

Whortleberries, the fruit of *Vaccinium Vitis idæa*, and cranberries, the fruit of *Vaccinium Oxycoccus* (L.), *Oxycoccus palustris* (Rich.), contain, according to Scheele, citric acid and a small quantity of malic acid.

VACUUM. The most usual method of producing a vacuum, or rather a highly rarefied atmosphere, is by the common air-pump. The exhaustion may be made much more complete by filling the exhausted receiver with carbonic acid gas, absorbing this gas by lime, and repeating the process several times. A vacuum may also be produced by driving the air out of a vessel with steam, and then condensing the steam by cooling.

In the barometric or Torricellian vacuum, there is nothing present but a very minute quantity of mercury-vapour. An excellent method of producing a vacuum has been contrived by Dr. Sprengel (Chem. Soc. J. xviii. 9). It consists in connecting the vessel to be exhausted with the upper part of a long vertical tube, down which a column of mercury is made to flow.

VALENE. Syn. with VALERONE.

VALENCIANITE. A name given by Breithaupt to orthoclase from the silver-mine of Valenciana in Mexico; related to adularin, and containing, according to Plattner, 66·82 per cent. silica, 17·58 alumina, 0·09 ferric oxide, and 14·80 potash.

VALENTINITE. The trimetric variety of native antimonious oxide (i. 323).

VALERACETONITRILE. $C^{26}H^{48}N^4O^6$. (Schlieper, Ann. Ch. Pharm. lix. 16.)—A body containing the elements of 4 at. valeronitrile, C^5H^9N, and 3 at. acetic acid, $C^2H^4O^2$, or of 1 at. valeronitrile and 3 at. valeracetamide, $C^5H^{10}(C^2H^3O)NO$. It is found in the neutral oil produced by distilling glue with potassium-chromate and sulphuric acid, and is obtained therefrom, in the same manner as valeronitrile (ii. 272), by repeated fractional rectification of the portion boiling between 68° and 90°.

Valeracetonitrile is a mobile colourless liquid, moderately soluble in water, and miscible in all proportions with alcohol and ether. It has an aromatic odour, makes a transient grease-spot on paper, has a specific gravity of 0·79, and boils between 68° and 71°. It is very inflammable, and burns with a faintly luminous flame. By heating with sulphuric acid, or with aqueous fixed alkalis, it is decomposed, with formation of ammonia, acetic acid, and valerianic acid:

$$C^{26}H^{48}N^4O^6 + 8H^2O = 4C^5H^{10}O^2 + 3C^2H^4O^2 + 4NH^3.$$

Chlorine and bromine decompose valeracetonitrile, with evolution of hydrochloric or hydrobromic acid.

VALERAL. $C^5H^{10}O = \left.\begin{matrix}C^5H^9O\\H\end{matrix}\right\}$ or $\left.\begin{matrix}C^5H^9\\H\end{matrix}\right\}O$. *Valeraldehyde. Valerianic Aldehyde. Amylic Aldehyde. Valeryl-hydride.*—This body was discovered by Dumas and Stas (Ann. Ch. Phys. [2] lxxiii. 145), who obtained it by oxidising amylic alcohol with nitric or chromic acid. It is also produced in the distillation of fusel-oil with sulphuric acid (Gaultier, Ann. Ch. Pharm. xliv. 127); by the dry distillation of a mixture of formate and valerate of calcium (Limpricht, *ibid.* xcvii. 370); by the action of manganese-peroxide and sulphuric acid upon gluten (Keller, *ibid.* xxxii. 31); of chromic acid on castor-oil (Arzbächer, *ibid.* lxxiii. 202), and of sulphuric anhydride on leucine (Schwanert, *ibid.* cii. 226), in the dry distillation of valerates, most easily, according to Ebersbach (*ibid.* cvi. 262), from valerate of calcium after addition of lime; and, lastly, by the dry distillation of lupulin-resin which has been exhausted with water, after addition of lime. (Personne, J. Pharm. [3] xxvi. 241, 329; xxvii. 22.)

Valeral, obtained by the dry distillation of valerates, was formerly regarded as isomeric, but not identical, with valeraldehyde produced by oxidation of amylic alcohol; the two products, however, invariably exhibit the same reactions, and appear to differ only in boiling-point, that of the product obtained by distillation of valerates being somewhat the higher of the two, and not constant, a peculiarity doubtless arising from admixture of other substances.

Preparation.—Valeral is usually prepared by oxidising amylic alcohol with chromate of potassium and sulphuric acid. The best way of proceeding, according to Parkinson (Ann. Ch. Pharm. xc. 114), is to allow a mixture of 11 pts. amylic alcohol, 16¼ pts. sulphuric acid, and 16¼ pts. water, to flow slowly into a lukewarm solution of 12¼ pts. potassium-chromate, whereby sufficient heat is produced to cause the greater part of the valeral to distil over; towards the end, however, the distillation must be assisted by external heating. The oily layer of the distillate is separated, and shaken up, first with potash-ley, to remove valerianic acid formed at the same time, and then with acid sodium-sulphite, with which it forms a crystalline compound; the resulting crystals are pressed and washed with alcohol, and the valeral is separated therefrom by distillation with carbonate of sodium.

Properties.—Colourless, very mobile, strongly refracting liquid, neutral to vegetable colours, having a burning bitter taste, a pungent fruity odour, and exciting coughing when inhaled, like most compounds of the amyl-group. Specific gravity = 0·8057 at 17°, 0·8224 at 0° (Kopp). Boiling point 96° to 97° under the ordinary pressure, 92·8° under a pressure of 740 mm. (Kopp). After keeping for some time, the boiling-point rises, and a considerable portion of the valeral passes into a modification, probably polymeric, having a higher boiling-point. Valeral is very inflammable, and burns with a bright flame, exhibiting a faint blue colour on the edges.

Valeral is insoluble in *water*, but mixes in all proportions with *alcohol*, *ether*, and *volatile oils*. It dissolves *iodine*, *phosphorus*, and various *resins*, but not sulphur, and mixes with strong sulphuric acid.

Decompositions.—1. Valeral heated above its boiling point is transformed into an isomeric compound, boiling between 150° and 200°.—The same compound is found in the mother-liquor of the preparation of valeral-sodium-sulphite (p. 974), and is also formed by heating that salt with dry sodium-carbonate (Parkinson). According to Limpricht, on the other hand (Ann. Ch. Pharm. cxiv. 244), valeral is not converted into an isomer by heat, neither is any such body found in crude valeral.

2. Valeral exposed to the air is gradually converted into valerianic acid; the oxidation is accelerated by contact with platinum-black. The same change is produced by the action of a mixture of *potassium-chromate* and *sulphuric acid*, and by other oxidising agents.—*Nitric acid* of ordinary strength converts it into nitrovalerianic acid.—3. By the prolonged action of *chlorine*, valeral is converted into dichlorovaleral, which unites with acid ammonium-sulphite, forming the crystalline compound $C^5H^8Cl^2O.NaHSO^3$ (Kündig, Ann. Ch. cxiv. 1).—4. By distillation with *phosphoric pentachloride*, valeral is converted into the chloride $C^5H^{10}Cl^2$, which, when treated with alcoholic potash, gives up hydrochloric acid, and yields the compound C^5H^9Cl. (Ebersbach.)

5. The ammonia-compound of valeral is converted by *sulphydric acid* into valeraldine, a base homologous with thialdine (p. 772).

6. When valeral-ammonia is evaporated with *hydrocyanic acid*, the valeral is converted into leucine, just as aldehyde is converted into alanine (i. 63):

$$\underset{\text{Valeral.}}{C^5H^{10}O} + CNH + H^2O = \underset{\text{Leucine.}}{C^6H^{13}NO^2}.$$

7. With *cyanic acid*, valeral forms an acid, $C^7H^{13}N^3O^2$ (Baeyer), homologous with trigenic acid (p. 883):

$$C^5H^{10}O + 3CNHO = CO^2 + C^7H^{13}N^3O^2.$$

8. Valeral fused with *potassium-hydrate*, gives off hydrogen and yields valerate of potassium:

$$C^5H^{10}O + KHO = C^5H^9KO^2 + H^2.$$

9. When valeral is heated with *lime*, amylic alcohol and valerate of calcium are produced; and on distilling the mixture, decomposition-products of the latter are obtained, including the two compounds, $C^6H^{12}O$ and $C^7H^{14}O$, apparently consisting of mixed acetones—the former isomeric with caproic aldehyde, the latter with œnanthol. (Fittig, Ann. Ch. Pharm. cxvii. 68.)

10. When valeral is treated with *sodium*, ultimately with aid of heat, hydrogen is evolved, and a yellow sodium-compound is formed, which is decomposed by heating to 120° with ethylic iodide, yielding an oil, $C^9H^{18}O$, isomeric with valerone (Ebersbach). Borodin, on the other hand (Zeitschr. Ch. Pharm. 1864, p. 353; Jahresb. 1864, p. 337), obtained a mixture which was decomposed by water into caustic soda, valerate of sodium, amylic alcohol, and two new bodies, $C^{10}H^{22}O$ and $C^{10}H^{18}O$. The first of these is a monatomic alcohol, isomeric or identical with decatylic alcohol. It is a colourless aromatic oil, boiling at 203·3° and having a specific gravity of 0·8569 at 0°. It forms ethers with acetic and benzoic acids, reacts like other monatomic alcohols with pentachloride of phosphorus, forms a sulpho-acid when treated wlth oil of vitriol, and with sodium a compound analogous to sodium-ethylate. Its formation from valeral is represented by the equation:

$$\underset{\text{Valeral.}}{3C^5H^{10}O} + Na^2 = \underset{\substack{\text{Decatylate}\\\text{of sodium.}}}{C^{10}H^{21}NaO^2} + \underset{\substack{\text{Valerate}\\\text{of sodium.}}}{C^5H^9NaO}.$$

$$\underset{\substack{\text{Decatylate}\\\text{of sodium.}}}{C^{10}H^{21}NaO} + H^2O = NaHO + \underset{\substack{\text{Decatylic}\\\text{alcohol.}}}{C^{10}H^{22}O}.$$

The second body, $C^{10}H^{18}O$, isomeric with camphol, is a light-yellow, tasteless, neutral oil, insoluble in water, easily soluble in alcohol and ether, having a specific gravity of 0·9027 at 17°. Its boiling-point rises from 250° to 280° and 290°, without perceptible change of composition.

11. Valeral, treated for fifteen days with *sodium-amalgam* and water, is partly converted into amylic alcohol. (Wurtz, Ann. Ch. Pharm. cxxxiv. 201.)

12. Alsberg (Jahresb. 1864, p. 485), by heating a mixture of 1 vol. valeral, 3 vols. amylic alcohol, and 1 vol. acetic acid, obtained a compound, $C^5H^{10}(C^5H^{11})^2O^2$, which he calls diamylvaleral, but which has in reality the composition of the diamylic ether of amylene-glycol (p. 974). The same compound is produced, together with valerianic acid and a little amylic alcohol, by treating valeral with ethylate of sodium and absolute alcohol:

$$\underset{\text{Valeral.}}{5C^5H^{10}O} + \underset{\substack{\text{Sodium-}\\\text{ethylate.}}}{2C^2H^5NaO} + H^2O = \underset{\substack{\text{Sodium-}\\\text{valerate.}}}{2C^5H^9NaO^2} + \underset{\substack{\text{Diamylic}\\\text{amylenate.}}}{C^5H^{10}(C^5H^{11})^2O^2} + \underset{\substack{\text{Ethylic}\\\text{alcohol.}}}{2C^2H^6O}.$$

COMPOUNDS AND DERIVATIVES OF VALERAL.

Valeral-ammonia, $C^5H^{10}O.NH^3 = C^5H^9(NH^4)O$.—Valeral absorbs ammonia-gas, forming a thick syrup, which, after several weeks, deposits crystals of valeral-ammonia (Parkinson). According to Ebersbach, the compound is more easily prepared by adding aqueous ammonia to valeral mixed with a thousand times its bulk of water: the liquid immediately becomes milky, and after a few hours deposits crystals, the formation of which goes on for several months. Valeral-ammonia melts when heated, is insoluble in water, but dissolves easily in alcohol and ether. It is decomposed by sulphydric acid with formation of valeraldine, and by hydrocyanic acid with formation of leucine (p. 973).

Compounds of Valeral with Alkaline Bisulphites.—The *ammonium-salt*, $C^5H^9(NH^4)SO^3$, is deposited in shining laminæ on distilling a mixture of acid ammonium-sulphite and valeral, and leaving the distillate to evaporate. It is decomposed by water, acids, and alkalis, with separation of valeral.—The *sodium-salt*, $2C^5H^9NaSO^4.2H^2O$, is nearly insoluble in absolute alcohol and in ether, sparingly soluble in cold water; it dissolves without decomposition in water at 70° to 80°, but when more strongly heated with water, it is decomposed with separation of valeral and sulphurous acid. Alkalis and acids decompose it immediately. The air-dried crystals effloresce in a vacuum over oil of vitriol.

Compounds of Valeral with Acetic and Benzoic Anhydrides.—The compound $C^5H^{10}O.C^4H^6O^3$ is formed by heating 1 at. valeral with 1 at. acetic anhydride, or 2 at. acetic acid, to 200° in a sealed tube for four to eight hours, and passes over at 195° on submitting the oily product to fractional distillation. It is a colourless, ethereal, mobile, neutral liquid, of specific gravity 0·963, boiling at about 195°, insoluble in water, easily miscible with alcohol and ether. It is not altered by water, but in contact with potash is easily resolved into acetic acid and valeral (Kolbe and Guthrie, Ann. Ch. Pharm. cix. 296).—The *benzoic compound*, $C^5H^{10}O.C^7H^{10}O^3$, is obtained in like manner by heating valeral with benzoic anhydride to 260°, and passes over on rectification at 264°. It is a white crystalline body, tasteless and inodorous, insoluble in water, melting at 111°, and boiling at 264°. Alkalis decompose it into valeral and benzoic acid. (Kolbe and Guthrie.)

Dichlorovaleral, $C^5H^8Cl^2O$, is produced by the action of chlorine on valeral (p. 973)

Methylvaleral, $C^5H^9(CH^3)O$, is obtained by distilling a mixture of equivalent quantities of alkaline valerate and acetate, agitating the oily distillate with potash, and rectifying till the boiling-point becomes constant. It is an oily liquid boiling at 120°. (Williamson, Ann. Ch. Pharm. lxxxi. 86.)

Diamylvaleral (so-called), $C^{15}H^{32}O^2$.—This compound, isomeric or identical with diamylic amylenate, $\left.\begin{matrix}(C^5H^{10})''\\(C^5H^{11})^2\end{matrix}\right\}O^2$, the neutral amylic ether of amylenic glycol, is produced, as already observed (p. 973), by heating valeral with amylic alcohol and acetic acid, or with sodium-ethylate and absolute alcohol. It has a disagreeable odour like that of the amyl-compounds, and of celery, is insoluble in water, of specific gravity 0·849 at 7°, and boils at 255°.—*Diethylvaleral* (so-called), $C^5H^{10}(C^2H^5)^2O^2$, prepared by heating 1 vol. valeral with 4 vols. alcohol and 1 vol. acetic acid, is slightly soluble in water, has a pleasant fruity odour, a specific gravity of 0·835 at 12°, and boils at 158·2°.—*Dimethylvaleral* (so-called), $C^5H^{10}(CH^3)^2O^2$, prepared with 1 vol. valeral, 2·5 vols. methylic alcohol, and 0·5 vol. acetic acid, has an agreeable odour, a specific gravity of 0·852 at 10°, and boils at 124°. (Alsberg.)

VALERAL-AMMONIA. See preceding article.

VALERALDEHYDE.
VALERALDIDE. } Syn. with VALERAL.

VALERALDINE. $C^{15}H^{31}NS^2$. (Beissenhirtz, Ann. Ch. Pharm. xc. 109.—Parkinson, *ibid.* xc. 119.)—An organic base, homologous with thialdine, produced by the action of sulphydric acid on valeral-ammonia suspended in water. It is a viscid oil, which does not solidify at −20°, has a strong unpleasant odour, is insoluble in water, soluble in alcohol and ether, and volatilises without decomposition. It has an alkaline reaction, and unites with hydrochloric acid, forming the salt $C^{15}H^{31}NS^2.HCl$, which crystallises in needles, and when dissolved in water, yields with silver-nitrate, first chloride and then sulphide of silver.

VALERAMIC ACID. Syn. with AMIDOVALERIC ACID (p. 978).

VALERAMIDE. $C^5H^9O.H^2N$.—The primary amide of valeric acid, first prepared by Dumas, Malaguti, and Leblanc (Compt. rend. xxv. 475, 658), and further examined by Dessaignes and Chautard (Ann. Ch. Pharm. lxviii. 333). It is produced by the action of 7 or 8 vols. strong aqueous ammonia on 1 vol. ethylic valerate, and sublimes on evaporating the liquid in shining laminæ. It melts at 100°, and sublimes at a somewhat higher temperature. It is insoluble in water, gives off ammonia when boiled with alkalis, but is not decomposed thereby at ordinary temperatures; when heated with phosphoric anhydride, or passed in the state of vapour over red-hot lime, it is resolved into water and valeronitrile, or cyanide of tetryl, C^5H^9N (ii. 272). When ignited with potassium, it gives off hydrogen and carburetted hydrogen, and forms cyanide of potassium.

VALERAMINE. The name originally given by Wurtz to amylamine.

VALERANILIDE. $C^{11}H^{15}NO = C^5H^{10}(C^6H^5)NO^2$.—*Phenylvaleramide.*—Produced by the action of valeric anhydride on aniline. Crystallises in lustrous needles or prisms, sparingly soluble in water, easily in alcohol and ether. Melts at 115°, and distils, for the most part unaltered, at a temperature above 220°. It is but slowly attacked by caustic potash, and it is only by fusion with hydrate of potassium that any appreciable quantity of aniline can be obtained from it. (Chiozza, Ann. Ch. Phys. [3], xxxix. 201.)

VALERATES. See VALERIC ACID (p. 976).

VALERENE. Syn. with AMYLENE and with BORNEENE.

VALERIAN. The root of *Valeriana officinalis* contains starch, extractive matter, resin (about 6 per cent.), an essential oil, valeric acid, and the ordinary plant-constituents.

The essential oil of valerian is obtained by distillation with water, 1,000 pts. of the root yielding from 4 to 12 pts. of oil. It is a pale-yellow or greenish liquid, having a strong odour of valerian, an aromatic taste, and strong acid reaction. Specific gravity = 0·90 to 0·93°. Becomes viscid at −15°, but does not solidify completely even at −40°. Begins to boil at about 200°, the boiling-point gradually rising to above 400°.

Crude valerian-oil is a mixture of several substances. According to Pierlot (Ann. Ch. Phys. [3], lvi. 291), 100 pts. of it contain:

$$\begin{array}{l}25 \text{ pts. camphene, } C^{10}H^{16} \text{ (borneene, valerene).}\\ \;\;5 \text{ pts. valeric acid.}\\ \left.\begin{array}{l}18 \text{ pts. stearoptene}\\ 47 \text{ pts. resin}\\ \;\;5 \text{ pts. water}\end{array}\right\}\text{or 70 pts. valerol.}\end{array}$$

On submitting the crude oil to fractional distillation, a yellowish oil passes over between 120° and 200°, containing nearly all the valeric acid and the borneene (i. 626); afterwards, according to Gerhardt (Ann. Ch. Phys. [3], vii. 275), an oxygenated oil, valerol; according to Pierlot, this oil may be resolved, by further fractional precipitation, and distillation over potassium-hydrate, into a camphor or stearoptene, a resin, valeric acid, and water.

VALERIANIC or **VALERIC ACID.** $C^5H^{10}O^2 = \left.\begin{array}{c}C^5H^9O\\H\end{array}\right\}O$.—*Delphinic Acid. Phocenic Acid. Butylcarbonic Acid. Baldriansäure.* (Chevreul [1817], *Recherches sur les corps gras*, pp. 99, 209.—Grote, Brandes' Arch. xxxiii. 160.—Trommsdorff and Ettling, Ann. Ch. Pharm. vi. 176.—Dumas and Stas, *ibid.* xxxv. 145.—Balard, *ibid.* lii. 311.—Meyer and Zenner, *ibid.* lv. 317.—Moro, *ibid.* lv. 330.—Redtenbacher, *ibid.* lix. 41.—Hlasiwetz, *ibid.* lxxi. 40.—Winckler, Repert. Pharm. xxvii. 169.—Krämer, Brandes' Arch. xl. 269; xliii. 21.—P. Morin. J. Pharm. [3], vii. 299.)—This acid, related to amylic alcohol in the same manner as acetic acid to ethylic alcohol, was first obtained by Chevreul, in 1817, from the fat of *Delphinum Phocæna*, and thence called delphinic or phocenic acid. Grote, in 1830, obtained from essential oil of valerian an acid which he designated as valerianic acid. This was shown by Trommsdorff and Ettling to be identical with Chevreul's phocenic acid, and the same acid was afterwards produced by oxidation of amylic alcohol, by Dumas and Stas, who established its composition and its relation to amylic alcohol.

Valeric acid appears to be somewhat widely diffused in the vegetable kingdom, being found in valerian-root, angelica-root, the root of *Athamanta oreoselinum*, the fruit and bark of the guelder rose (*Viburnum Opulus*), the bark of the elder-tree, and in many plants of the composite order. It is also found in many animal oils and other animal secretions. It is a frequent product of the oxidation of fats and of the putrefaction of albuminous substances, &c. Amylic alcohol yields, by oxidation, valerianic acid, together with valeral and amylic valerate.

Preparation.—By oxidation of amylic alcohol.—A mixture of 1 pt. amylic alcohol and 2 pts. strong sulphuric acid is allowed to flow slowly into a solution of 5 pts. acid potassium-chromate in water; and when the first action, which takes place spontaneously, is over, the mixture is heated for some time in a flask provided with a vertical condensing-tube, in order to convert the valeral produced in the first instance into valeric acid.

The liquid is then distilled; the distillate saturated with carbonate of sodium; the amylic valerate contained in it is distilled off; and the dry residue of sodium-valerate is dissolved in an equal weight of water and distilled with sulphuric acid ($\frac{1}{2}$ to $\frac{3}{5}$ pt. oil of vitriol to 1 pt. sodium-salt). The distillate consists of an aqueous solution of valeric acid, surmounted by an oily layer consisting of a definite hydrate, $C^5H^{10}O^2.H^2O$, from which the pure acid or hydric valerate, $C^5H^{10}O^2$, may be obtained by rectification, a milky aqueous distillate passing over at first, and afterwards, at 175°, the pure acid, in the form of a clear oily liquid.

Properties.—Pure valeric acid, or hydric valerate, is a colourless mobile oil, having a sour burning taste, and a strong peculiar odour, like that of valerian-oil, somewhat also like that of butyric acid and decayed cheese. Specific gravity = 0·937 at 16° (Dumas and Stas); 0·9378 at 19·6°, and 0·9555 at 0° (Kopp); 0·9558 at 15° (Mendelejef). Index of refraction, 1·3952 (Delffs). It is active or inactive to polarised light, according as it has been prepared from active or inactive amylic alcohol: the active modification produces a rotation of 17° to the left in a tube 50 centimetres long (Pedler, Chem. Soc. J. xxi. 74). It remains liquid and transparent at −15°, makes transient grease-spots on paper, boils at 175° (Dumas and Stas; Persin): at 175·8° under a pressure of 746 mm. (Kopp). The specific gravity of its vapour, when determined at a sufficiently high temperature, is 3·66; calc. for 2 vols. = 3·53.

Hydric valerate, ($C^5H^{10}O^2$), dissolves in 30 pts. water at 12°, mixes in all proportions with alcohol and ether, and dissolves abundantly in strong acetic acid. It dissolves water, and forms an oily hydrate, $C^5H^{10}O^2.H^2O$ (commonly called the trihydrate, from having been regarded as $C^{10}H^{18}O^3.3H^2O$), which separates on decomposing a valerate with sulphuric acid not too much diluted; or on adding chloride of calcium, or other dehydrating salt, or phosphoric anhydride, to an aqueous solution of the acid. This hydrate is oily, like the pure hydric valerate, but has a higher specific gravity (0·950, according to Trautwein), and a lower boiling-point; when it is heated, aqueous valeric acid first passes over, and afterwards pure hydric valerate.

Valeric acid mixes with oil of turpentine, and dissolves phosphorus, camphor, and some resins.

Decompositions.—1. Valeric acid vapour passed through a red-hot tube, is resolved into carbonic oxide, carbonic anhydride, and a mixture of hydrocarbons of the olefine group (ethylene, tritylene, and tetrylene), sometimes also mixed with marsh-gas (Hofmann, Chem. Soc. Qu. J. iii. 121).—2. When an *electric current* is passed through a solution of potassic valerate, the valeric acid is resolved, with absorption of oxygen into tetryl and carbonic anhydride:

$$\underset{\substack{\text{Valeric}\\\text{acid.}}}{2C^5H^{10}O^2} + O = \underset{\text{Tetryl.}}{C^8H^{18}} + 2CO^2 + H^2O.$$

The tetryl is, however, converted by further oxidation into tetrylene and water:

$$C^8H^{18} + O = 2C^4H^8 + H^2O;$$

or it is oxidised to tetrylic oxide, $(C^4H^9)^2O$, which then reacts with the valeric acid to form tetrylic valerate (Kolbe, Ann. Ch. Pharm. lxix. 257).—3. By *potassic permanganate* in alkaline solution, valeric acid is oxidised to carbonic acid, oxalic acid, butyric acid, and its lower homologues, together with a volatile solid acid, perhaps angelic acid (Neubauer, Ann. Ch. Pharm. cvi. 59).—4. Valeric acid dissolves, with evolution of heat, in strong *sulphuric acid*, apparently forming a conjugated acid.—5. Strong *nitric acid* slowly converts it into nitrovaleric acid.—6. With *chlorine* and *bromine* it also forms substitution-products. It dissolves *iodine*, but without forming an iodated acid.—7. With *pentachloride* or *oxychloride of phosphorus*, it forms valeric chloride or valeric anhydride.—8. When heated with *pentasulphide of phosphorus*, it forms thiovaleric acid, a liquid having an extremely offensive odour, and probably consisting of $C^5H^{10}OS$. (Ulrich, Ann. Ch. Pharm. cx. 281.)

Valerates.—Valeric acid is monobasic, forming neutral salts, $C^5H^9MO^2$, and a few acid and basic salts. The valerates are produced by direct saturation. They are unctuous to the touch, inodorous when dry, but smell of valeric acid when moist, especially if they are also warmed; they have a sweetish taste, with somewhat pungent after-taste. Most of them dissolve in water, a few also in alcohol; many of them rotate on the water in the act of dissolving. By dry distillation, they yield chiefly valerene and valerone. A mixture of valerate and formate subject to dry distillation yields valeral; a mixture of valerate and acetate yields, in like manner, methylvaleral (p. 975). The soluble valerates are decomposed by the electric current, with formation of carbonic acid, tetrylene, and tetrylic valerate.

Valerates are decomposed by mineral acids and by many organic acids: *e.g.* acetic, tartaric, citric, malic acid, &c., with separation of valeric acid. Butyric acid does not decompose them; on the other hand, butyrates heated with valeric acid yield free butyric acid. On this reaction is founded a method of separating butyric and valeric acids, by partial saturation with potash, whereby only valerate of potassium is at first produced. When a mixture of acetic and valeric acids is partially neutralised with potash, and heated, acid acetate of potassium remains behind. (Liebig, see ANALYSIS, i. 250.) Valeric acid is further distinguished from butyric acid, which it resembles in many respects, by the behaviour of its cupric salt (*infra*).

Valerate of Ammonium, $C^5H^9(NH^4)O^2$, easily gives off ammonia when heated. It dissolves freely in water and in alcohol. When heated with phosphoric anhydride, it yields valeronitrile. This salt is formed in the putrefaction of organic bodies, and is a frequent constituent of mouldy cheese.—The *potassium-salt*, $C^5H^9KO^2$, solidifies on evaporation, to an amorphous, white, deliquescent, saline mass, having an alkaline reaction, very soluble in water and in strong alcohol, soluble in less than 3·9 pts. of absolute alcohol at 20°. It melts at 140°, and decomposes at a stronger heat. When distilled with arsenic, it yields a heavy, oily, alliaceous, fuming liquid, probably the cacodyl of valeric acid (Gibbs, Sill. Am. J. [2], xv. 118).—The *sodium-salt* crystallises, by spontaneous evaporation in dry air at 32°, in cauliflower-like masses, extremely deliquescent, very soluble in water, and even in absolute alcohol, melting at 140°.—The *lithium-salt*, $2C^5H^9LiO^2.H^2O$, crystallises from the syrupy solution, in spherical warty masses.

Valerate of Barium, $C^{10}H^{18}Ba''O^4.2H^2O$, crystallises by spontaneous evaporation in shining, easily friable crystals, which dissolve in 2 pts. water at 15°, in 1 pt. at 20°, exhibiting a very brisk rotation, and are sparingly soluble in alcohol. They give off from 2 to 2½ per cent. water on exposure to the air at 25°, the rest (about 7 per cent.) when heated; the dry salt decomposes at a dull red heat, giving off an inflammable gas, probably tetrylene, yielding a strong-smelling distillate of valeral, with a little valerone, and leaving carbonate of barium mixed with a little charcoal.—The *calcium-salt*, $C^{10}H^{18}Ca''O^4.H^2O$, crystallises by slow evaporation in stellate groups of prisms and needles, easily soluble in water and in ordinary alcohol, sparingly soluble in absolute alcohol, melting with decomposition at 150°. A mixture of 6 pts. valerate of calcium and 1 pt. lime yields, by dry distillation, a mixture of valerone and valeral.—The *strontium-salt* crystallises in four-sided tables.—The *magnesium-salt* is obtained, by slow evaporation, in tufts of transparent prisms, moderately soluble in water, slightly soluble in alcohol.

The *cupric salt* separates from the blue-green solution of cupric carbonate in the aqueous acid, in green monoclinic prisms containing $C^{10}H^{18}Cu''O^4.H^2O$, soluble in water and in alcohol. When concentrated valeric acid is added to a solution of cupric acetate, and the liquid agitated, anhydrous cupric valerate separates after a while in oily drops, which in five to twenty minutes change into a greenish-blue crystalline powder of the hydrated salt. According to Larocque and Huraut (J. Pharm. [3] ix. 430), this reaction distinguishes valeric from butyric acid, which, when added to cupric acetate, immediately forms a crystalline precipitate.

Iron-salts.—*Neutral ferric valerate* has not been obtained in the separate state. Valerate of sodium added to ferric chloride, throws down a mixture of neutral and basic salt, which, after drying, forms a dark brick-red, amorphous powder. Iron dissolves in aqueous valeric acid with evolution of hydrogen, forming *ferrous valerate.*

Lead-salts.—The *neutral salt*, $C^{10}H^{18}Pb''O^4$, separates from solution by slow evaporation, in shining, easily fusible laminæ.—A *basic salt*, $C^{10}H^{18}Pb''O^4.2PbO$, is obtained, by treating valeric acid with excess of litharge, exhausting with cold water, and evaporating the filtrate in a vacuum over oil of vitriol, in hemispherical groups of shining needles, infusible and sparingly soluble in water.

Mercury-salts.—The *neutral mercuric salt* separates, on mixing mercuric chloride with valerate of sodium, in slender white needles, which are also deposited on boiling the basic salt with water, and leaving the filtrate to cool. The basic salt, which has a red colour, is obtained by moderately heating the neutral salt, or by dissolving mercuric oxide in warm concentrated valeric acid. It is insoluble in cold water, and is decomposed by boiling water into the neutral salt and a red residue.—The *mercurous salt* separates in small needles from a solution of mercurous oxide in hot concentrated valeric acid.

The *silver-salt*, $C^5H^9AgO^2$, separates on evaporation, in white shining laminæ. On adding an alkaline valerate to nitrate of silver, a curdy precipitate is formed which gradually becomes crystalline. The salt blackens on exposure to light, and is decomposed by heat.

Zinc-salt, $C^{10}H^{18}Zn''O^4$.—Metallic zinc dissolves slowly in aqueous valeric acid. The aqueous acid saturated by boiling with zinc-carbonate and filtered hot, deposits the anhydrous zinc-salt in nacreous scales resembling boric acid. The same salt is obtained by precipitation. According to Duclou, it dissolves in 50 pts. cold and 40 pts. boiling water, in 17·5 pts. cold and 16·7 pts. boiling alcohol; according to Wittstein, it dissolves in 90 pts. cold water, in 60 pts. cold alcohol of 80 per cent., in 500 pts. cold and 200 pts. boiling ether. The aqueous solution gives off valeric acid on boiling. The salt melts at 140°, and decomposes at a higher temperature.—A *hydrated salt*, $C^{10}H^{18}Zn''O^4.12H^2O$, is obtained by mixing equivalent quantities of hydric valerate and recently precipitated zinc-carbonate with a small quantity of water, and drying at a gentle heat. It does not differ in appearance from the anhydrous salt, gives off all its crystallisation-water at 100°, and dissolves in 44 pts. of cold water, the solution, when evaporated, yielding crystals of the anhydrous salt (Wittstein). Valerate of zinc is used as a remedy in nervous disorders. The commercial salt is said to be sometimes contaminated with butyrate, the presence of which may be detected by separating the acid, and testing with acetate of copper in the manner already described (p. 977).

Substitution-derivatives of Valeric Acid.

Amidovaleric Acid, $C^5H^{11}NO^2 = C^5H^9(NH^2)O^2$. *Valeramic Acid. Valeramidic Acid.*—This acid, which might also be regarded as *oxyvaleramic acid*, $\left.\begin{matrix}H^2\\(C^5H^8O)''\\H\end{matrix}\right\}\begin{matrix}N\\O\end{matrix}$, was found by Gorup-Besanez (Ann. Ch. Pharm. xcviii. 15), together with leucine (amidocapric acid) in the pancreas of an ox. It is produced artificially by the action of ammonia on an alcoholic solution of bromovaleric acid:

$$C^5H^9BrO^2 + 2NH^3 = C^5H^{11}NO^2 + NH^4Br.$$

(Cahours, Ann. Ch. Pharm. Suppl. ii. 83.—Fittig and Clark, Zeitschr. f. Chem. 1865, p. 503). It might probably also be formed, similarly to the homologous amic acids, by reducing nitrovaleric acid with sulphydric acid, and by the action of hydrocyanic and hydrochloric acids on butyral.

Amidovaleric acid was prepared from the pancreas of the ox by extraction with cold water. The solution was boiled, the filtrate mixed with excess of baryta-water to separate phosphoric acid, and the filtrate evaporated to a syrup over the water-bath; whereupon it deposited a mixture of leucine and amidovaleric acid, which were separated by fractional solution in alcohol of specific gravity 0·82, the amidovaleric acid being much less soluble than the leucine. It was ultimately purified by recrystallisation from strong alcohol.

Amidovaleric acid closely resembles leucine (amidocapric acid), but is less soluble in water and in alcohol, especially in the latter; it is insoluble in ether. It unites with acids, forming crystallisable compounds, which are much more soluble than the corresponding leucine-salts. It dissolves easily, and without decomposition, in aqueous alkalis, forming, for the most part, crystallisable compounds.

When heated in a glass tube, it melts and sublimes, with partial decomposition, giving off alkaline vapours having a strong odour of herring-pickle, probably tetrylamine. When heated in the air, it burns quickly with a bluish flame.

Bromovaleric Acid, $C^5H^9BrO^2$.—Produced by the action of bromine on valeric acid at 140°—150° (Cahours, Ann. Ch. Pharm. Suppl. ii. 74), or on valerate of silver (Borodine, *ibid.* cxix. 121). It is a colourless heavy oil, having a pungent odour, and boiling, according to Cahours, between 226° and 230°, without perceptible decomposition; according to Borodine, on the other hand, it is decomposed by boiling, giving off hydrobromic acid, yielding a distillate containing valeric acid, and apparently valeral, and leaving a carbonaceous residue.

Bromovaleric acid separates valeric acid from valerates. Its compounds with the alkalis and alkaline earths are easily soluble and not crystallisable. The silver-salt is white, insoluble, and very unstable. (Borodine.)

This acid is easily etherified; its ethylic ether boils between 190° and 194°.

Chlorovaleric Acids. *Trichlorovaleric* or *Chlorovalerisic acid*, $C^5H^7Cl^3O^2$, is formed by passing chlorine-gas into hydric valerate in the dark, the liquid being cooled at first, and afterwards warmed to 50° or 60°; the excess of chlorine is expelled by a stream of carbonic anhydride. Trichlorovaleric acid is an oily liquid, very viscid at $-18°$; not very mobile at ordinary temperatures, but perfectly mobile at 30°. It is inodorous, has a sharp burning taste, is heavier than water, and decomposes at 110°—120°, with evolution of hydrochloric acid. In contact with water it forms a very fluid hydrate, which sinks to the bottom of the water. The acid dissolves in aqueous alkalis, but is precipitated therefrom by acids in its original state. The aqueous solution forms, with nitrate of silver, a precipitate soluble in nitric acid. (Dumas and Stas.)

Tetrachlorovaleric or *Chlorovalerosic acid*, $C^5H^6Cl^4O^2$, is formed by the prolonged action of an excess of chlorine on valeric acid in sunshine, the action being ultimately assisted by heating the liquid to 60°. It is a colourless, inodorous, semifluid oil, having a sharp, burning, bitter taste, heavier than water, not solidifying at $-15°$, not volatile, decomposing when heated above 150°. It unites with water, forming an oily hydrate,

$C^5H^6Cl^4O^2.H^2O$, and dissolves in a large quantity of water, easily also in alcohol and ether. The solutions, after a while, contain free hydrochloric acid. The acid is easily decomposed by fixed alkalis, but not by ammonia.

Tetrachlorovaleric acid decomposes carbonates. The alkaline tetrachlorovalerates are easily soluble in water; the rest insoluble or sparingly soluble.—The *silver-salt*, $C^5H^5AgCl^4O^2$, obtained by precipitation from the ammonium-salt, is white, slightly soluble in water, easily in nitric acid; the solution, when exposed to light, deposits chloride of silver. The dry salt decomposes slowly in the dark, forming chloride of silver, and a substance which makes grease-spots on paper—probably trichloroxyvaleric acid, $C^5H^7Cl^3O^3$. (Dumas and Stas.)

Nitrovaleric Acid, $C^5H^9(NO^2)O^2$. (Dessaignes, Ann. Ch. Pharm. lxix. 274.) —Formed by the action of strong nitric acid at the boiling heat on valeric acid; crystallises from the acid solution in thin needles, from water in rhombic plates. It sublimes at 100°, but its boiling-point is much higher.—*Nitrovalerate of lead* is easily soluble, and crystallises in thin prisms.—The *ferric salt* is insoluble, and resembles ferric succinate.—The *barium-* and *calcium-salts* are very soluble, the latter crystallising in needles.—The *silver-salt*, $C^5H^8Ag(NO^2)O^2$, crystallises from boiling water in slender prisms.

Dessaignes is of opinion that the acid designated as nitrovaleric acid may perhaps be nitro-angelic acid, $C^5H^7(NO^2)O^2$.

VALERIAN-OIL. See VALERIAN (p. 975).

VALERIC ALDEHYDE. Syn. with VALERAL (p. 973).

VALERIC ANHYDRIDE. $C^{10}H^{18}O^3 = (C^5H^9O)^2O$. *Valeric Oxide. Valeric Valerate. Anhydrous Valeric Acid.* (Chiozza, Ann. Ch. Pharm. lxxxiv. 106.) —Prepared by decomposing 6 at. dry valerate of potassium with rather more than 1 at. oxychloride of phosphorus, and purified by washing the distillate with carbonate of sodium, dissolving it in ether, and evaporating. It is a colourless, moderately mobile oil, not miscible with water. When recently prepared it has a faint and not unpleasant odour of apples, but when rubbed between the fingers, it emits the offensive odour of valeric acid. Specific gravity = 0·934 at 15°. Boiling-point, 215°. Vapour-density = 6·23. It slowly absorbs *water*, and is converted into valeric acid. When heated with an *alkali*, it is instantly converted into a valerate. On gently warming it with a small quantity of *potassic hydrate*, a violent action takes place, and free valeric acid is formed as well as potassic valerate:

$$(C^5H^9O)^2O + KHO = C^5H^9O.K.O + C^5H^9O.H.O.$$

With *alcohol* it quickly forms ethylic valerate; hence the ether used in purifying it must be free from alcohol.—By *ammonia* it is quickly converted into valeramide; by *aniline* into valeranilide.

Benzovaleric anhydride, $C^7H^5O.C^5H^9O.O$, is produced by the action of benzoic chloride on potassic valerate (i. 558), and other double anhydrides containing valeryl may be formed in a similar manner.

VALERIC BROMIDE, C^5H^9OBr, is produced by the action of phosphoric pentabromide on valeric acid. It is a liquid boiling at 143°. (Béchamp.)

VALERIC CHLORIDE, C^5H^9OCl, is produced by the action of phosphoric oxychloride on valerate of sodium (Moldenhauer), or of phosphorous chloride on valeric acid (Béchamp). It is a colourless, mobile, fuming liquid, having a specific gravity of 1·005 at 6°, and boiling between 115° and 120°; easily decomposed by water into hydrochloric and valeric acid. (Béchamp, Compt. rend. xlii. 224.—Moldenhauer, Ann. Ch. Pharm. civ. 111.)

VALERIC ETHERS. The valerates of methyl, ethyl, and amyl are prepared by distilling valerate of sodium with sulphuric acid and the corresponding alcohols.

Methylic Valerate, $C^5H^9(CH^3)O^2$, is a colourless liquid, having an odour like that of wood-spirit and valerian together. Specific gravity = 0·8869 at 15°; 0·9015 at 0°. Boils at 116°. Specific heat (between 45° and 21°) = 0·491. (Kopp.)

Ethylic Valerate, $C^5H^9(C^2H^5)O$, is a colourless liquid, having a fruity odour, also like that of valerian. Specific gravity = 0·866 at 18° (Kopp), 0·894 at 0° (Otto). Index of refraction = 1·3904 (Delffs). Boils at 133° (Otto; Kopp; Berthelot); at 131° (Delffs). Dissolves sparingly in water, easily in alcohol. Ammonia converts it into valeramide.

Ethylic valerate dissolves sodium, with little or no evolution of hydrogen. Wanklyn (Chem. Soc. J. xvii. 371), by heating 2 grms. sodium with 6 grms. ethylic valerate and 7·5 grms. pure ether, obtained an oily body, having approximately the composition of valeryl:

$$\underset{\text{Ethylic valerate.}}{2(C^5H^9O.C^2H^5.O)} + Na^2 = \underset{\text{Sodium-ethylate.}}{2C^2H^5NaO} + \underset{\text{Valeryl.}}{(C^5H^9O)^2}.$$

Geuther and Greiner (Jahresb. 1865, p. 319) obtained no valeryl, but the sodium-salt of a crystallisable acid, and an oily body, which, when distilled, yielded, as principal product, a liquid boiling, like the so-called diamylvaleral (p. 974), between 240° and 260°.

Amylic Valerate, $C^5H^9(C^5H^{11})O$, is prepared as above, and is likewise formed in the preparation of valeric acid by oxidising amylic alcohol with sulphuric acid and potassic chromate, being contained in the oily liquid separated from the valerate of sodium (p. 975). It is an oily liquid, having an agreeable fruity odour. Specific gravity = 0·8645 at 17°. Boiling-point 187° to 188° (Kopp); 196° (Balard). Vapour-density = 6·1. A solution of this ether in 6 to 8 pts. alcohol has a strong odour of apples, and is used for aromatising sugar, &c.

Cetylic Valerate, $C^5H^9(C^{16}H^{33})O$, has a specific gravity of 0·852 at 20°, melts at 25°, solidifies again at 20°, and boils at 280°—290°. (E. Dollfus, Ann. Ch. Pharm. cxxxi. 283.)

VALERIC IODIDE, C^5H^9OI, is prepared by distilling an anhydrous valerate with iodide of phosphorus, and rectifying the distillate over mercury. It is a heavy nearly colourless liquid, boiling at 108°, quickly decomposed by water and by alcohol. (Cahours, Compt. rend. xliv. 1252.)

VALERIC OXIDES. The *protoxide*, $(C^5H^9O)^2O$, has been already described as valeric anhydride (p. 979).

Valeric Peroxide, $C^{10}H^{18}O^4 = (C^5H^9O)^2O^2$, is produced by the action of hydrated barium-peroxide on valeric anhydride. It is a heavy oily liquid, slightly soluble in water, exploding slightly when heated, and acting as an oxidising agent when suspended in water. (Brodie, Proc. Roy. Soc. xii. 655.)

VALERINS. Glycerides produced by heating valeric acid with glycerin. The delphinin or phocenin which Chevreul obtained by treating dolphin-oil with alcohol, was probably a mixture of trivalerin with monovalerin and divalerin.

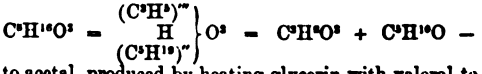
Monovalerin, $C^8H^{16}O^4 = (C^3H^5)'''(HO)^2.(C^5H^9O^2) = C^5H^{10}O^2 + C^3H^8O^3 - H^2O$. —Produced by heating valeric acid with excess of glycerin to 200° for three hours, and purified with potash-ley, &c. in the usual way. It is also formed by the action of hydrochloric acid gas on a mixture of glycerin and valeric acid. Oily neutral liquid having a faint odour, and a specific gravity of 1·100 at 16°. Mixes with half its bulk of water to a clear liquid; separates, on addition of more water, and mixes with 100 vols. water to a liquid having the character of an emulsion. By contact with the air for some weeks it becomes acid, and then contains free valeric acid, but the alteration is not attended with any perceptible absorption of oxygen. Alcohol and hydrochloric acid decompose it, even in the cold, forming ethylic valerate and glycerin. Aqueous ammonia slowly converts it into valeramide.

Divalerin, $C^{13}H^{24}O^5 = (C^3H^5)'''.HO.(C^5H^9O^2)^2 = C^3H^8O^3 + 2C^5H^{10}O^2 - 2H^2O$. —Produced by heating glycerin with valeric acid to 275°. Oily liquid, having a disagreeable fishy odour and a bitter aromatic taste. Specific gravity = 1·059 at 16°. Solidifies at −40°, but remains soft and transparent; does not mix readily with water. Its reactions are similar to those of monovalerin.

Trivalerin, $C^{18}H^{32}O^6 = (C^3H^5)'''(C^5H^9O^2)^3 = C^3H^8O^3 + 3C^5H^{10}O^2 - 3H^2O$. —Produced by heating divalerin to 220° with 8 or 10 times its weight of valeric acid. It is a neutral oily liquid, having a faint unpleasant odour, insoluble in water, but soluble in alcohol and ether; decomposed by alcohol and hydrochloric acid like the other valerins. (Berthelot.)

VALERISIC ACIDS, in the nomenclature of Laurent and others, are substitution-products of valeric acid, in which 3 at. hydrogen are replaced by chlorine or other radicles, *e.g.* chlorovalerisic acid, $C^5H^7Cl^3O^2$. In like manner, those products in which 4 at. hydrogen are thus replaced, are called valerosic acids.

VALERODICHLORHYDRIN, $(C^3H^5)'''(C^5H^9O)OCl^2$, is produced by heating epichlorhydrin (i. 894) with chloride of valeryl to 100°. It is a mobile liquid, smelling like amylic acetate, having a specific gravity of 1·149 at 11°, and boiling at 245°, under a pressure of 737 mm. (Truchot, Ann. Ch. Pharm. cxxxviii. 297.)



VALEROGLYCERAL. $C^8H^{16}O^3 = \left.\begin{matrix}(C^3H^5)''' \\ H \\ (C^5H^{10})''\end{matrix}\right\} O^3 = C^3H^8O^3 + C^5H^{10}O - H^2O$.—A compound analogous to acetal, produced by heating glycerin with valeral to 170°—180° for 24 hours. It is a liquid boiling between 224° and 228°. Specific gravity = 1·027 at 0°. Vapour-density, obs. = 5·526; calc. = 5·544. It is insoluble in water, has only a faint odour, but is decomposed by moist air, and then emits an odour like that of valeral. (Harnitz-Harnitzky and Menschutkin, Ann. Ch. Pharm. cxxxvi. 126; Jahresb. 1865, p. 506.)

Similar compounds are obtained with acetic and benzoic aldehydes.

VALEROL. $C^6H^{10}O$?—The neutral oxygenated constituent of valerian-oil p. 975). It was first prepared and examined by Gerhardt (Ann. Ch. Phys. [3], vii. 275), and afterwards found by Personne (Compt. rend. xxxvii. 309) in the volatile oil of lupulin. It is prepared by rapidly distilling valerian-oil in a stream of carbonic anhydride, whereupon borneene (valerene), borneol, and valeric acid pass over first, and afterwards valerol. The latter is heated to 200°, for some time, in an atmosphere of carbonic anhydride, then cooled in ice, and the valerol which crystallises out is washed with aqueous sodic carbonate, rectified several times in carbonic anhydride, and crystallised by cooling (Gerhardt). According to Pierlot (Ann. Ch. Phys. [3], lvi. 294), it must be distilled over hydrate of potassium, to free it completely from valeric acid.

Valerol crystallises at 0° in colourless transparent prisms. It melts at 20°, then remains liquid at ordinary temperatures, and does not solidify till cooled to 0°. In the liquid state it floats on water. It is slightly soluble in water, easily soluble in alcohol, ether, and volatile oils. According to Pierlot, its boiling-point is not constant, but varies during distillation from 200° to 430° without remaining stationary at any intermediate point; in fact, valerol is not a definite compound, but a mixture of the stearoptene of valerian-oil (p. 975), with resin and a little water. According to Gerhardt and Cahours, it is converted into valeric acid by atmospheric oxidation, and when heated with potassic hydrate gives off hydrogen, and yields valerate and carbonate of potassium:

$$C^6H^{10}O + 3KHO + H^2O = C^5H^9KO^2 + K^2CO^3 + 3H^2.$$

According to Pierlot, on the other hand, it is not converted into valeric acid by exposure to the air, or by treatment with any oxidising agent, and if quite free from valeric acid is not acted upon by potash.

VALEROLACTIC ACID. $C^5H^{10}O^3$.—Syn. with ethyl-lactic acid (see Lactic Ethers, iii. 463). According to J. Clark (Jahresb. 1865, p. 319), it is produced by heating bromovaleric acid with silver-oxide and water. Its zinc-salt crystallises readily.

VALERONE. $C^9H^{18}O = \left.\begin{matrix}C^5H^9O\\C^4H^9\end{matrix}\right\} = \left.\begin{matrix}C^5H^9\\C^4H^9\end{matrix}\right\}O$.—*Valeryl-butyl. Valene. Valeroyl-butyloxide. Dibutylacetone. Dibutylcarbonoxyd.*—This body, the ketone of valeric acid, is produced by the distillation of valerates, the calcium-salt being generally used. It was first prepared by Löwig (Pogg. Ann. xlii. 412), mixed, however, with a large quantity of valeral; pure valerone was first obtained by Ebersbach (Ann. Ch. Pharm. cvi. 268), who separated the valeral by means of acid sulphite of sodium. The best mode of preparing it is to distil valerate of calcium with one-sixth of its weight of lime; the quantity obtained, however, is but small, probably because the greater part of it is resolved into valeral and tetrylene: $C^9H^{18}O = C^5H^{10}O + C^4H^8$. Valerone is a transparent, colourless, mobile liquid, having a pleasant ethereal odour and burning taste. It is lighter than water, does not mix with it, but dissolves in alcohol and ether. It boils at 165°, does not combine with acid sulphite of sodium, and is decomposed by sodium and by pentachloride of phosphorus only when heated.

VALERONITRILE. C^5H^9N.—Syn. with Cyanide of Tetryl, $C^4H^9.CN$. (See Cyanides, ii. 272.)

VALERONYL. Löwig's name for the hydrocarbon C^4H^9

VALEROSIC ACIDS. See Valerisic Acids (p. 980).

VALEROXYL. Syn. with Valeryl.

VALEROYL. A name applied to the hydrocarbon C^5H^9, according to which denomination, valerene or amylene may be designated as hydride of valeroyl, $C^5H^9.H$, &c., valerone as valeroyl-butyloxide, $C^5H^9.C^4H^9.O$, &c.

VALERUREID. Syn. with Valerylurea. (See Carbamides, i. 753.)

VALERYL. C^5H^9O. *Valeroxyl.*—The radicle of valeric acid and its derivatives. According to Wanklyn, it is obtained in the free state by the action of sodium on ethylic valerate (p. 979).

The bromide, chloride, &c. of valeryl are described as valeric bromide, &c. (p. 979); the protoxide as valeric anhydride (p. 979); the peroxide as valeric peroxide (p. 980).

VALERYLAMIDIC ACID. Syn. with Amidovaleric Acid (p. 978).

VALERYL-BUTYL. Syn. with Valerone.

VALERYLENE. C^5H^8. (Reboul, Ann. Ch. Pharm. cxxxi. 238; cxxxii. 117; cxxxv. 372; Jahresb. 1864, p. 505; 1865, p. 509.)—This hydrocarbon, homologous with acetylene, is obtained by heating bromide of amylene with concentrated alcoholic potash to 140° for several hours, distilling the liquid separated from the product by water, and collecting that which passes over from 44° to 46°. It is a colourless very mobile liquid, which floats on water, and is nearly insoluble therein. It has a pungent alliaceous odour, boils at 44° to 46° under a pressure of 745 mm., has a vapour-density of 2·356 (calc. 2·354). It is not absorbed by an ammoniacal solution of cuprous chloride.

Bromine-compounds of Valerylene.—Valerylene shaken up with strong aqueous hydrobromic acid, becomes hot and is converted into a red oil, which, after washing with alkaline water, yields, by fractional distillation, the two following compounds:

Monohydrobromate of valerylene, $C^5H^8.HBr$, boiling at 112°;
Dihydrobromate of valerylene, $C^5H^8.2HBr$, „ 170°—175°.

The former, which is the chief product, is distinguished from the isomeric body monobromamylene, C^5H^9Br, boiling at 115°, chiefly by its property of forming with bromine a liquid compound, $C^5H^8.HBr.Br^2$, whereas monobromamylene forms with bromine a crystallisable compound, $C^5H^9Br.Br^2$.

When bromine is added by drops to valerylene cooled by a freezing mixture, a fresh quantity of valerylene added before the red colour appears, then more bromine, and so on alternately, a heavy oil is formed containing two liquid bromine-compounds, $C^5H^8Br^2$ and $C^5H^8Br^4$, in various proportions. If the addition of bromine be discontinued when no more instantaneous decoloration takes place, the product consists mainly of the dibromide; in the contrary case, provided the action be sufficiently prolonged, nothing but tetrabromide is obtained. In sunshine the tetrabromide forms in an hour or two, together with the crystalline compound, $C^5H^7Br.Br^4$ (*a*).

Tetrabromide of Valerylene, $C^5H^8Br^4$, is a thick very heavy liquid, which does not solidify at −10°; it is isomeric with the (probably solid) bromide of dibromamylene, $C^5H^8Br^2.Br^2$.

Dibromide of Valerylene, $C^5H^8Br^2$, is obtained by distilling the above-mentioned mixture, and collecting the portion which passes over below 200°. It boils at 166°—172°, and unites quickly with bromine, forming a tetrabromide, from which, however, on exposure to sunshine, crystals of a compound, $C^5H^7Br.Br^4$(*b*) separate, differing from the isomeric body (*a*) in crystalline form, behaviour when heated, and solubility in ether. Hence it appears probable that there are two isomeric tetrabromides of valerylene, $C^5H^8Br^4$ and $C^5H^8Br^2.Br^2$, each of which yields a corresponding substitution-product. Wurtz's diallyl is, perhaps, homologous with valerylene.

Bromovalerylene, C^5H^7Br.—When the above-mentioned mixture of dibromide and tetrabromide of valerylene is distilled to dryness with alcoholic potash-solution, and the distillate mixed with water, a heavy oil separates, which is resolved by fractional distillation into the three following compounds:—(1) *Dibromide of valerylene,* $C^5H^8Br^2$ (boiling at 170°—175°), mixed with a small quantity of the compound $C^5H^8Br(C^2H^3O)$; (2) *Bromovalerylene,* C^5H^7Br, boiling at 125°—130°; and (3) *Valylene,* C^5H^6, boiling at 45° to 50°, together with a small quantity of valerylene. The formation of these bodies is represented by the equations:

$C^5H^8Br^2 - HBr = C^5H^7Br$. Bromovalerylene.
$C^5H^8Br^4 - 2HBr = C^5H^6$. Valylene.
$C^5H^8Br^2 - Br^2 = C^5H^8$. Valerylene.

Bromovalerylene is partially decomposed by distillation, and becomes coloured by keeping. It unites at low temperatures with bromine, forming the compounds $C^5H^7Br^3$ and $C^5H^7Br^5$. When shaken up with an ammoniacal solution of *cuprous chloride*, it is immediately converted into a yellow solid body, consisting of cuprous valylide, C^5H^5Cu, together with cuprous bromide and oxide:

$$C^5H^7Br + Cu^2O = C^5H^5Cu + CuBr + H^2O.$$

VALERYL-HYDRIDE. Syn. with VALERAL (p. 973.)

VALERYLUREA. See CARBAMIDES (i. 753).

VALONIA. The commercial name of the large cups of the prickly-cupped oak (*Quercus Ægilops*), an infusion of which is used in tanning leather. They contain tannin and gallic acid. The tannin does not yield pyrogallic acid by dry distillation, and is but slightly precipitated by sulphuric acid, even from very concentrated solutions.

VALYL. Kolbe's name for TETRYL or BUTYL.

VALYLENE. C^5H^6. (Reboul, Ann. Ch. Pharm. cxxxv. 372; Jahresb. 1865, p. 510.)—This hydrocarbon is found, as above mentioned, among the products of the action of alcoholic potash on dibromide of valerylene, passing over on distillation, together with a little valerylene, between 45° and 50°. It may be obtained pure by treating the mixture with ammoniacal cuprous chloride, which converts the valylene into cuprous valylide, C^5H^5Cu, but does not act upon the valerylene. The cuprous valylide (which may also be obtained by the action of ammoniacal cuprous chloride on bromovalerylene), is washed by decantation with ammoniacal water, then with a little alcohol, and dried. It decomposes quickly when heated, leaving a black residue. It is decomposed by bromine with inflammation, and by fuming nitric acid with incandescence. An ammoniacal silver-solution converts it into a silver-compound of analogous composition and properties.

To separate the valylene, the copper-compound is warmed with a very slight excess of dilute hydrochloric acid, and the hydrocarbon which distils over is condensed by a freezing mixture. Valylene is a light liquid boiling at about 50°, having an alliaceous odour, recalling also that of prussic acid. When brought in contact by drops with *bromine* in a freezing mixture, it forms a crystalline mass saturated with a thick liquid, the crystalline portion consisting of bromide of valylene, $C^5H^6Br^6$, and the liquid being a mixture of the compounds $C^5H^6Br^6$, $C^5H^6Br^4$, and perhaps $C^5H^6Br^2$.

VALYLIDES. See the last article.

VANADATES.
VANADIC ACID. } See Vanadium, Oxides of (p. 989).

VANADINBRONZITE. This name is given by Schafhäutl (N. Jahresb. f. Min. 1844, p. 721) to a mineral from the Serpentine of Bracco, on the coast of Genoa, containing 49·50 per cent. silica, 5·55 alumina, 18·13 lime, 14·12 magnesia, 3·28 ferrous oxide, 3·65 vanadium-pentoxide, 3·75 soda, and 1·77 water. It is coarsely laminar, with one distinct and two indistinct directions of cleavage, has a nacreous lustre and greenish-grey colour, and is translucent in thin laminæ. Hardness less than 4. Specific gravity = 3·255.

VANADINITE. *Vanadate*, or more properly, *Vanadato-chloride of lead.* See Vanadates (p. 991).

VANADIOUS ACID.
VANADITES. } See Vanadium, Oxides of (p. 988).

VANADIUM. *Atomic weight*, 51·2; *Symbol*, V.—A metal usually classed with molybdenum and tungsten, but shown by recent investigations to belong to the same series as arsenic, antimony, and bismuth.

Del Rio, in 1801 (Gilb. Ann. lxxi. 7), found in the lead-ore of Zimapan, in Mexico, a new metal which he designated as *erythronium*; subsequently, however, he regarded it as impure chromium.—Sefström, in 1830 (Pogg. Ann. xxi. 43) found in the bar-iron obtained from the ores of Taberg in Sweden, and especially in the refinery slags, a new metal which he named vanadium, after the Scandinavian deity *Vanadis*; Wöhler (*ibid.* xxi. 49) then showed that the lead-ore of Zimapan consisted of lead-vanadate, and that Del Rio's erythronium was not chromium, but vanadium. Subsequently this metal has been found in several other ores, most abundantly in lead-vanadate from Wanlockhead in Scotland, and from La Plata; in smaller quantity also in pitchblende, in many iron-ores, and the pig-iron obtained from them; also on the native copper of Lake Superior, probably as phosphate; and in several kinds of clay, to the amount of 0·02 to 0·07 per cent. Vanadium appears, therefore, to be somewhat widely diffused, but it never occurs in large quantity, and has, indeed, been hitherto regarded as one of the rarest of the metals. Quite recently, however, a more productive source of it has been discovered by Roscoe (Proc. Roy. Soc. xvi. 223) in some of the copper-bearing beds of the Lower Keuper sandstone of the Trias, worked at Alderley Edge and Mottram St. Andrews, in Cheshire. In working up a pure cobalt-ore from Mottram, a large quantity of a lime-precipitate was obtained, containing nearly 2 per cent. of vanadium.

Extraction.—1. From the refinery slag of the Taberg iron-ore.—The finely-pulverised slag is deflagrated with nitre and carbonate of sodium; the fused mass is digested with boiling water; and into the crude solution of potassium-vanadate thus obtained, lumps of sal-ammoniac are introduced, whereby vanadate of ammonium, which is insoluble in a saturated solution of sal-ammoniac, is deposited in crystalline grains. This salt, when ignited in an open vessel, leaves pure vanadium-pentoxide. (Berzelius.)

2. From certain kinds of pig-iron.—The grey pig-iron smelted from the oolitic iron-ores of Westbury, in Wiltshire, contains, according to Riley (Chem. Soc. J. xvii. 21), about 0·7 per cent. vanadium, which becomes concentrated in the graphitic residue left on dissolving the iron in hydrochloric acid. On treating this residue with potash-ley, to free it from silica, and burning the remaining graphite with free access of air, a mixture of tetroxide and pentoxide of vanadium is obtained. (Riley.)

3. From native vanadate of lead.—The solution of the mineral in nitric acid is freed from lead and arsenic by sulphydric acid; the blue filtered liquid is boiled for a short time, and then evaporated to dryness at a moderate heat; the dark-red residue is boiled with a saturated solution of ammonium-carbonate, which is added from time

to time; and the liquid is filtered at the boiling heat. On cooling, it deposits white needles of ammonium-vanadate, which may be purified by recrystallisation. (Johnston, N. Edinb. J. of Sc. v. 166, 318.)

4. From the lime-precipitate, obtained, as already mentioned, in working the cobalt-ore of Mottram in Cheshire.—This precipitate, containing mainly arsenic, iron, lead, copper, vanadium, and lime, with sulphuric and phosphoric acids, was first well furnaced with ground coal, to drive off the greater portion of the arsenic; then roasted with one quarter of its weight of soda-ash, so as to convert the vanadium into a soluble vanadate; and on lixiviation, arsenic and the heavy metals were completely thrown down by sulphuretted hydrogen. The deep blue solution was neutralised by ammonia, the precipitated vanadium-oxide dried and oxidised by nitric acid, and the crude vanadic acid thus obtained was boiled out with a saturated solution of ammonium-carbonate. The slightly soluble ammonium-vanadate was washed and recrystallised. In order to prepare pure vanadic acid from this salt, it was roasted, and the powdery acid thus obtained was suspended in water into which ammonia-gas was passed; the dissolved ammonium-vanadate was separated by filtration from a residue containing silica, phosphates, &c. The pentoxide obtained by heating this salt was free from phosphorus. A second method of preparing the pure vanadium-pentoxide consists in decomposing the pure oxychloride with water, and freeing the acid from any traces of silica by exposure to hydrofluoric acid gas. Great difficulty was experienced in obtaining vanadium free from phosphorus; all the native vanadates contain large quantities of phosphorus. (Roscoe.)

Metallic vanadium remains when vanadium-nitride is heated to whiteness in ammonia-gas (Uhrlaub, Pogg. Ann. ciii. 134), but it does not appear to have been obtained quite pure.

Berzelius, by igniting vanadium-pentoxide with potassium, and washing out the fused mass with water, obtained a brilliant metallic-looking powder, which has been hitherto regarded as pure vanadium; but Roscoe has shown that it is an oxide.

Compounds of Vanadium.—Berzelius, to whose elaborate research published in 1831 (Pogg. Ann. xxii. 1), we were till lately indebted for nearly all our knowledge of the vanadium-compounds, obtained three oxides, to which he assigned the formulæ VO, VO^2, VO^3 ($V = 68{\cdot}5$, $O = 8$); he also obtained a chloride corresponding to the highest oxide, namely VCl^3. According to these results, vanadium was regarded as a metal belonging to the same class as chromium, molybdenum, and tungsten. This view, however, was somewhat difficult to reconcile with the observed fact of the isomorphism of certain vanadium-compounds with analogous compounds belonging to the phosphorus and arsenic groups; the mineral vanadinite, for example, which is a compound of lead-vanadate and lead-chloride, is isomorphous with apatite, pyromorphite, and mimetesite—minerals consisting of calcium-phosphatochloride, lead-phosphatochloride, and lead-arsenatochloride. This anomaly induced several chemists to suspect that vanadium might really belong to the phosphorus and arsenic group of elements. Baumgarten, in particular (Jahresb. 1865, p. 219), was led to this conclusion by observing among the last crystallisations from the soda mother-liquors at Schöningen, colourless crystals, consisting of phosphatofluoride of sodium, $2Na^3PO^4.NaF.19H^2O$, in which the phosphorus was partly replaced by arsenic, and to a greater extent by vanadium (the crystals containing from 0·89 to 1·06 per cent. vanadic oxide). Baumgarten likewise obtained perfectly similar crystals, containing the same proportion of vanadium, by direct synthesis.

Such observations could not, however, be regarded as having much weight against the definite experimental results of Berzelius, which showed beyond doubt that, if the lowest of the three oxides obtained by him is a monoxide, VO, the highest must be a trioxide, VO^3. This conclusion was based:—1. On the constant loss of weight which the highest oxide undergoes on reduction in hydrogen at a red heat.—2. On the action of chlorine on this reduced oxide, whereby a volatile chloride is formed, and a residue of vanadic oxide obtained, which is found to be exactly one-third of the quantity originally taken for reduction in hydrogen. These results may be represented by the following equations:

$$(1)\quad VO^3 + H^2 = VO + H^2O^2$$
$$(2)\quad 3VO + Cl^6 = VO^3 + 2VCl^3.$$

But the recent experiments of Roscoe, whilst fully confirming these fundamental results of Berzelius, and proving that if the atomic weight assigned to vanadium by that chemist, viz. 68·5, be correct, the formulæ of the oxides must be VO, VO^2, VO^3, or V^2O, V^2O^2, V^2O^3, and that of the volatile chloride VCl^3, have shown, on the other hand,—1. That the supposed metal of Berzelius is really an oxide.—2. That the quantities of oxygen in this and the three higher oxides, united with the same weight of vanadium, are to one another as the numbers 2, 3, 4, 5—these four oxides being, in fact, represented by the formulæ V^2O^2, V^2O^3, V^2O^4, V^2O^5, analogous to those of the oxides of nitrogen (neglecting the monoxide).—3. That the supposed trichloride obtained by Berzelius is an oxychloride, $VOCl^3$, related to vanadic oxide, V^2O^5, in the same manner as phosphoric oxychloride is related to phosphoric oxide. The quantitative results of the reduction of vanadic oxide in hydrogen, and the treatment of the reduced oxide by chlorine, are represented on this view by the equations:

$$V^2O^5 + 2H^2 = V^2O^3 + 2H^2O.$$
$$3V^2O^3 + 6Cl^2 = V^2O^5 + 4VOCl^3.$$

Roscoe has further pointed out that vanadic oxide forms, with metallic oxides, two classes of salts, analogous in composition to the orthophosphates and metaphosphates (p. 991). It may therefore be concluded that vanadium exhibits in all respects the characters of a metal belonging to the phosphorus and arsenic group.

VANADIUM, BROMIDES OF. No bromide of vanadium has yet been obtained in the free state. The so-called tribromide obtained, by Schafarik, is an oxybromide, $VOBr^3$ (p. 992).—The *tetrabromide*, VBr^4, is probably contained in the blue solution of vanadium-tetroxide in hydrobromic acid. This solution dries up in a vacuum to a blue gum, which becomes violet-brown when heated, but is still perfectly soluble in water. The aqueous solution gives off a greenish-grey precipitate with ammonia.

VANADIUM, CHLORIDES OF. None of these compounds are known in the free state.—The *tetrachloride*, VCl^4, probably exists in solution and in two isomeric modifications:

α. Vanadic acid, boiled with strong hydrochloric acid, gives off chlorine and forms a blue solution, which, when concentrated by evaporation, yields a blue syrup not precipitated by alcohol. When perfectly dried by heat, it leaves a brown oxychloride no longer quite soluble in water.

β. Vanadium-tetroxide dissolved in strong hydrochloric acid forms a brown solution, which, when left to evaporate, yields a black liquid, becoming brown again on dilution. The brown solution turns blue when evaporated by heat, or on addition of strong sulphuric acid. Ammonia added to the brown solution forms a greenish-brown precipitate, insoluble in water.

Several oxychlorides of vanadium have been obtained (p. 992).

VANADIUM, DETECTION AND ESTIMATION OF. 1. *Blowpipe Reactions.*—All compounds of vanadium heated with *borax* or *phosphorus-salt*, produce a clear bead, which is colourless if the quantity of vanadium is small, yellow if it is large; in the inner flame the bead acquires a beautiful green colour.

2. *Reactions in Solution.*—Vanadium-dioxide (the metallic vanadium of Berzelius), may be obtained in solution by the action of nascent hydrogen on a solution of the pentoxide in sulphuric acid. The solution of hypovanadious sulphate thus obtained has a lavender colour, and is an extremely powerful reducing agent. (See p. 987.)

Vanadium-tetroxide, or vanadious oxide (the dioxide of Berzelius) dissolves in acids, forming salts called vanadious salts, most of which are of a blue colour. Vanadious salts form, with the *hydrates* and *monocarbonates* of the *fixed alkalis*, a greyish-white precipitate of hydrated vanadious oxide, which dissolves in a moderate excess of the reagent, but is precipitated by a large excess, in the form of a vanadite of the alkali-metal.—*Ammonia* in excess produces a brown precipitate, soluble in pure water, but insoluble in water containing ammonia.—*Ferrocyanide of potassium* forms a yellow precipitate, which turns green on exposure to the air.—*Sulphuric acid* produces no precipitate.—*Sulphide of ammonium* forms a black-brown precipitate, soluble in excess.—*Tincture of galls* forms a finely-divided black precipitate, which gives to the liquid the appearance of ink.

Vanadium-tetroxide also unites with the more basic metallic oxides, forming salts called vanadites, all of which are insoluble, except those of the alkali-metals. The solutions of the alkaline vanadites are brown, but when treated with *sulphydric acid*, they acquire a splendid red-purple colour, arising from the formation of a sulphur-salt.—*Acids* colour them blue, by forming a double vanadious salt; *tincture of galls* colours them blackish-blue. The insoluble vanadites, when moistened or covered with water, become green, and are converted into vanadates.

Vanadium-pentoxide, or vanadic oxide, reacts for the most part as an acid oxide, uniting with bases to form salts called vanadates. These salts are all more or less soluble in water; the barium- and lead-salts, however, are very sparingly soluble. The alkaline vanadates are sparingly soluble in cold water, especially if it contains free alkali or another alkaline salt: *e.g.*, vanadate of ammonium is nearly insoluble in water containing sal-ammoniac: hence, on treating a solution of potassium-vanadate with excess of sal-ammoniac, a precipitate of ammonium-vanadate is produced.

The aqueous solutions of the vanadates are coloured red by the stronger acids, but the mixture often becomes colourless again after a while. They give orange-red precipitates with the *antimonious, plumbic, cupric,* and *mercuric salts.*—*Sulphydric acid* produces, in neutral solutions of the vanadates, a mixed precipitate of sulphur and hydrated vanadious oxide; in acid solutions it merely throws down sulphur, and reduces the vanadic oxide to vanadious oxide.—*Sulphide of ammonium* imparts to solutions of the vanadates a brown-red colour, and, on adding an acid to the solution, a light-brown precipitate is formed, consisting of vanadic sulphide mixed with sulphur; the liquid, at the same time, generally acquires a blue colour.

Vanadic and chromic acids are the only acids whose solutions are red; they are distinguished from one another by the vanadic acid becoming blue, and the chromic acid green, by deoxidation.

When a solution of vanadic acid, or an acidulated solution of an alkaline vanadate, is shaken up with ether containing *hydric peroxide,* the aqueous solution acquires a red colour, like that of ferric acetate, while the ether remains colourless. This reaction will serve to detect the presence of 1 pt. of vanadic acid in 40,000 pts. of liquid. The red colouring is also produced by ozonised oil of turpentine, and by hydric peroxide alone; also by ordinary ether not containing hydric peroxide. Chromic acid, even in considerable quantity, does not interfere with the reaction. (G. Werther, J. pr. Chem. lxxxiii. 195.)

3. *Estimation and Separation.*—Vanadium, in the form of free pentoxide or tetroxide, is estimated by reducing it to trioxide by ignition in a stream of hydrogen.

In solutions of vanadites, the vanadium is precipitated by mixing the solution with excess of mercuric chloride, and then with ammonia. The precipitate, consisting of mercuric vanadite and chloride of dimercurammonium (white precipitate) is ignited in contact with the air, whereupon vanadium-pentoxide remains mixed only with a small quantity of mercuric oxide, from which it is separated by solution in carbonate of ammonia.

When vanadic acid is dissolved in a liquid not containing any other fixed constituents, it may be separated as vanadium-pentoxide by evaporation, and if volatile acids or ammonia are also present, by igniting the residue.

Vanadic acid may be separated from many acids and other substances, by causing it to unite with ammonia, expelling the excess of ammonia by evaporation, and then adding a saturated solution of sal-ammoniac, in which vanadate of ammonia is insoluble. The precipitate is then washed on a filter, first with solution of sal-ammoniac, then with alcohol, and the ammonia driven off by ignition. This method serves to separate vanadium from the alkali-metals.

Vanadium may be separated from many of the preceding metals by the solubility of its sulphide in sulphide of ammonium; and from others, which are precipitated from their acid solutions by sulphydric acid, by acidulating the liquid and passing sulphydric acid gas through it; the vanadium then remains dissolved in the form of vanadious oxide.

From *lead, barium,* and *strontium,* vanadic acid may be separated by fusion with acid sulphate of potassium; on treating the fused mass with water, sulphate of lead, barium, or strontium remains, while vanadate of potassium is dissolved. Sulphuric acid cannot be used to effect this separation, because the precipitated sulphate always carries down with it a portion of the vanadium. (Berzelius.)

Vanadium may also be separated from these metals, and from all others which form insoluble carbonates, by fusing the vanadate with twice its weight of sodium-carbonate, digesting the fused mass in water, and washing the undissolved portion. (v. Hauer, J. pr. Chem. lxix. 385.)

Atomic Weight of Vanadium.—The atomic weight of this metal has been determined in two ways:—*a.* By igniting vanadium-pentoxide, V^2O^5, in pure dry hydrogen-gas, whereby it is reduced to the trioxide, V^2O^3. The atomic weight of vanadium is then determined from he equation:

$$V = \frac{8\,(5b-3a)}{a-b},$$

where a = the weight of vanadium-pentoxide taken;
„ b = „ vanadium-trioxide obtained.

Roscoe, in four experiments, obtained the following results:

No.	Weight of pentoxide taken.	Weight of trioxide obtained.	Atomic weight of vanadium.
1.	7·7397	6·3827	51·26
2.	6·5819	5·4296	51·39
3.	5·1895	4·2819	51·48
4.	5·0450	4·1614	51·35

The mean atomic weight deduced from these experiments is 51·37, with a mean error of ± 0·066. Berzelius found, as a mean of four experiments, that 120·927 pts. of the pentoxide yielded 100 pts. of trioxide, which gives, according to the above equation, V = 52·55.[*] The difference is probably due to the fact that the vanadium employed by Berzelius contained a trace of phosphorus, which prevented the complete reduction.

β. By the analysis of vanadium-oxytrichloride or vanadyl-trichloride, $VOCl^3$.—The chlorine in this compound was estimated both by Gay-Lussac's volumetric process, and by weight-analysis. Nine volumetric determinations give 61·306 per cent. chlorine; seven gravimetric determinations give 61·241 per cent. From these numbers an atomic weight of 51·05 is obtained for vanadium. The mean of 51·05 and 51·37 (the number obtained from the reduction experiments), viz. 51·21, is regarded as the true atomic weight of vanadium. (Roscoe.)

VANADIUM, FLUORIDES OF. Vanadium-tetroxide dissolves in hydrofluoric acid, forming a blue solution, which yields, by spontaneous evaporation, a greenish syrup and green crystals, probably consisting of the hydrated tetrafluoride. It forms light-blue double salts with the fluorides of potassium and sodium.

Vanadium-pentoxide also dissolves in warm aqueous hydrofluoric acid, and the solution, evaporated at 40°, leaves a white mass, which dissolves perfectly in water, but, when strongly heated, leaves an insoluble residue of pure vanadium-pentoxide.

VANADIUM, IODIDES OF. Vanadium-tetroxide dissolves in aqueous hydriodic acid, forming a blue solution, which turns green in contact with the air, and yields, by spontaneous evaporation, a brown semifluid mass, soluble with black-brown colour in water.

VANADIUM, NITRIDES OF. There are two compounds of vanadium and nitrogen.—The *mononitride*, VN, obtained by heating the compound of vanadium-oxytrichloride with ammonium-chloride to whiteness, in a current of ammonia-gas, is a greyish-white powder, unalterable in the air. It gave, by analysis, 78·6 per cent. vanadium and 21·4 nitrogen, the formula VN requiring 77·8 vanadium and 20·2 nitrogen. (Roscoe.)

Vanadium-dinitride, VN^2, was obtained by Uhrlaub (Pogg. Ann. ciii. 134), who however assigned to it a different formula, by heating the ammonium-oxychloride in ammonia-gas to a moderate temperature. It is a black powder, which is strongly acted upon by warm nitric acid, and gives off ammonia when fused with potash.

VANADIUM, OXIDES OF. The oxides of vanadium are analogous in composition to the oxides of nitrogen, excepting that the one corresponding to the protoxide or monoxide of nitrogen has not yet been obtained. The complete series is as follows:

Vanadium-monoxide (hyp.)	V^2O
Vanadium-dioxide, Hypovanadious oxide, or Vanadyl	V^2O^2
Vanadium-trioxide, or Hypovanadic oxide	V^2O^3
Vanadium-tetroxide, Vanadious oxide, or Vanadious anhydride	V^2O^4
Vanadium-pentoxide, Vanadic oxide, or Vanadic anhydride	V^2O^5

Vanadium-dioxide, V^2O^2.—This, the lowest oxide of vanadium yet obtained, was regarded by Berzelius as metallic vanadium. As it enters into many vanadium-compounds (just as uranyl enters into the uranic compounds), it may be appropriately called vanadyl.

Vanadium-dioxide is obtained by reducing either of the higher oxides with potassium (Berzelius), or by passing the vapour of vanadium-oxytrichloride, ($VOCl^3$), mixed with excess of hydgogen, through a combustion-tube containing red-hot charcoal (Schafarik, Ann. Ch. Pharm. cix. 85; Jahresb. 1859, p. 168). As obtained by the second process, it forms a light-grey glittering powder, or a metallically lustrous crystalline crust, having a specific gravity of 3·64, brittle, very difficult to fuse, and a conductor of electricity. When heated to redness in the air, it takes fire and burns to black oxide. It is insoluble in sulphuric, hydrochloric, and hydrofluoric acid, but dissolves easily in nitromuriatic acid, forming a dark-blue liquid. (Schafarik.)

The dioxide may be prepared in solution by the action of nascent hydrogen, evolved by metallic zinc, cadmium, or sodium-amalgam, on a solution of vanadic acid in sulphuric acid. After passing through all shades of blue and green, the liquid acquires a permanent lavender tint, and then contains the vanadium in solution as dioxide, or as hypovanadious salt. This compound absorbs oxygen more rapidly than any other

---

[*] Berzelius, regarding the highest oxide as VO^3, $[O = 8]$ and supposing it to be reduced to VO by ignition in hydrogen, calculated the atomic weight of the metal from the equation $V = \frac{8(3b - a)}{a - b}$, which gives, according to his experiments, $V = 68·55$, and, according to Roscoe's, $V = 67·37$; this is really the molecular weight of the dioxide.

The aqueous solutions of the vanadates are coloured red by the stronger acids, but the mixture often becomes colourless again after a while. They give orange-red precipitates with the *antimonious*, *plumbic*, *cupric*, and *mercuric salts*.—*Sulphydric acid* produces, in neutral solutions of the vanadates, a mixed precipitate of sulphur and hydrated vanadious oxide; in acid solutions it merely throws down sulphur, and reduces the vanadic oxide to vanadious oxide.—*Sulphide of ammonium* imparts to solutions of the vanadates a brown-red colour, and, on adding an acid to the solution, a light-brown precipitate is formed, consisting of vanadic sulphide mixed with sulphur; the liquid, at the same time, generally acquires a blue colour.

Vanadic and chromic acids are the only acids whose solutions are red; they are distinguished from one another by the vanadic acid becoming blue, and the chromic acid green, by deoxidation.

When a solution of vanadic acid, or an acidulated solution of an alkaline vanadate, is shaken up with ether containing *hydric peroxide*, the aqueous solution acquires a red colour, like that of ferric acetate, while the ether remains colourless. This reaction will serve to detect the presence of 1 pt. of vanadic acid in 40,000 pts. of liquid. The red colouring is also produced by ozonised oil of turpentine, and by hydric peroxide alone; also by ordinary ether not containing hydric peroxide. Chromic acid, even in considerable quantity, does not interfere with the reaction. (G. Werther, J. pr. Chem. lxxxiii. 195.)

3. *Estimation and Separation.*—Vanadium, in the form of free pentoxide or tetroxide, is estimated by reducing it to trioxide by ignition in a stream of hydrogen.

In solutions of vanadites, the vanadium is precipitated by mixing the solution with excess of mercuric chloride, and then with ammonia. The precipitate, consisting of mercuric vanadite and chloride of dimercurammonium (white precipitate) is ignited in contact with the air, whereupon vanadium-pentoxide remains mixed only with a small quantity of mercuric oxide, from which it is separated by solution in carbonate of ammonia.

When vanadic acid is dissolved in a liquid not containing any other fixed constituents, it may be separated as vanadium-pentoxide by evaporation, and if volatile acids or ammonia are also present, by igniting the residue.

Vanadic acid may be separated from many acids and other substances, by causing it to unite with ammonia, expelling the excess of ammonia by evaporation, and then adding a saturated solution of sal-ammoniac, in which vanadate of ammonia is insoluble. The precipitate is then washed on a filter, first with solution of sal-ammoniac, then with alcohol, and the ammonia driven off by ignition. This method serves to separate vanadium from the alkali-metals.

Vanadium may be separated from many of the preceding metals by the solubility of its sulphide in sulphide of ammonium; and from others, which are precipitated from their acid solutions by sulphydric acid, by acidulating the liquid and passing sulphydric acid gas through it; the vanadium then remains dissolved in the form of vanadious oxide.

From *lead*, *barium*, and *strontium*, vanadic acid may be separated by fusion with acid sulphate of potassium; on treating the fused mass with water, sulphate of lead, barium, or strontium remains, while vanadate of potassium is dissolved. Sulphuric acid cannot be used to effect this separation, because the precipitated sulphate always carries down with it a portion of the vanadium. (Berzelius.)

Vanadium may also be separated from these metals, and from all others which form insoluble carbonates, by fusing the vanadate with twice its weight of sodium-carbonate, digesting the fused mass in water, and washing the undissolved portion. (v. Hauer, J. pr. Chem. lxix. 385.)

Atomic Weight of Vanadium.—The atomic weight of this metal has been determined in two ways:—*a*. By igniting vanadium-pentoxide, V^2O^5, in pure dry hydrogen-gas, whereby it is reduced to the trioxide, V^2O^3. The atomic weight of vanadium is then determined from he equation:

$$V = \frac{8\,(5b-3a)}{a-b},$$

where a = the weight of vanadium-pentoxide taken;
„ b = „ vanadium-trioxide obtained.

Roscoe, in four experiments, obtained the following results:

No.	Weight of pentoxide taken.	Weight of trioxide obtained.	Atomic weight of vanadium.
1.	7·7397	6·3827	51·26
2.	6·5819	5·4296	51·39
3.	5·1895	4·2819	51·48
4.	5·0450	4·1614	51·35

chloride mixed with a vanadous salt. The precipitate, when ignited, leaves vanadium-tetroxide, still retaining a small quantity of mercuric oxide.

Vanadium-pentoxide, V^2O^5. *Vanadic Oxide. Vanadic Anhydride. Anhydrous Vanadic Acid.*—This is the highest oxide of vanadium. It is prepared by igniting vanadate of ammonium in an open platinum-crucible; when cold, it has a rusty-yellow colour, lighter in proportion as the oxide is more finely divided.—The pentoxide may also be obtained by dissolving the impure tetroxide in strong sulphuric acid, and evaporating the solution. Pure vanadic sulphate, $V^2O^5.2SO^3.H^2O$ (p. 617—there called "basic vanadic sulphate," and represented by the formula $VO^3.2SO^3$), then remains as a light, orange-coloured, sandy powder, which, on ignition, leaves the pure pentoxide (Fritzsche, J. pr. Chem. liii. 93).—Very pure vanadium-pentoxide is likewise obtained by decomposing vanadyl-trichloride with water (Schafarik):

$$2VOCl^3 + 3H^2O = V^2O^5 + 6HCl.$$

Pure vanadium-pentoxide has a more or less reddish-yellow colour: it is tasteless, reddens moistened litmus-paper, and dissolves in 1,000 pts. of water, forming a light-yellow solution. When heated, it melts without decomposition, if kept from contact with deoxidising substances; and the red liquid crystallises on cooling, becoming incandescent at the moment of solidification, in consequence of the heat then suddenly evolved. The solidified mass is yellowish-red, and according to Nordenskjold (Pogg. Ann. cxii. 160), contains more or less distinct rhombic crystals.

Vanadium-pentoxide is not altered by simple ignition, but is easily reduced by heating with potassium, charcoal, hydrogen, carburetted hydrogen, organic substances, &c. In solution, it is also easily reduced by sulphurous or sulphydric acid, and even by nitrous acid; also by stannous salts, and by sugar, alcohol, and other organic substances, the colour of the solution then changing from red or yellow to green and blue. The solution of the acid in hydrochloric acid gives off chlorine when evaporated; tincture of galls colours the solution of vanadic acid black, on standing, in consequence of reduction.

Vanadic Hydrate or *Vanadic Acid*, $H^2O.V^2O^5$ + aq. or $2HVO^3.H^2O$, is obtained, by treating a somewhat concentrated solution of an anhydrovanadate of alkali-metal with nitric acid, as a bulky flocculent precipitate, which dries up in the air to a light brown-red powder having the composition just mentioned. It gives off 1 at. water over oil of vitriol, and when dried by heat, forms solid lumps, having a conchoïdal fracture.

Vanadium-pentoxide dissolves in the stronger acids, forming red or yellow solutions, which are partly decolorised by boiling and evaporation, especially when they contain excess of vanadium; many of these solutions yield crystalline compounds by spontaneous evaporation. (See Phosphatovanadic Acid, iv. 686; and Sulphates of Vanadium, v. 617). Alkalis added to the solutions, form precipitates soluble in excess. The solutions are easily reduced by oxidisable substances.

Vanadates.—Vanadium-pentoxide unites with bases much more readily than with acids. When fused with alkaline carbonates, it eliminates 3 at. carbonic anhydride, forming orthovanadates, analogous to the orthophosphates, *e.g.*:

$$3(Na^2O.CO^2) + V^2O^5 = 3Na^2O.V^2O^5 + 3CO^2.$$

It also forms metavanadates, analogous to the metaphosphates, and two series of acid vanadates or anhydrovanadates, viz.:

$$\begin{array}{llll}
\text{Orthovanadates, } M^3VO^4 & = \left.\begin{matrix}(VO)'''\\ M^3\end{matrix}\right\}O^3 & = & 3M^2O.V^2O^5.^* \\
\text{Metavanadates, } MVO^3 & = \left.\begin{matrix}(VO)'''\\ M\end{matrix}\right\}O^2 & = & M^2O.V^2O^5. \\
\text{Divanadates, } M^2V^4O^{11} & = 2MVO^3.V^2O^5 & = & M^2O.2VO^5. \\
\text{Trivanadates, } M^2V^6O^{16} & = 2MVO^3.2V^2O^5 & = & M^2O.3V^2O^5.
\end{array}$$

Metavanadate of lead occurs native, as *Dechenite*; the orthovanadate also, combined with lead-chloride, as *Vanadinite*. *Descloizite* is a diplumbic vanadate, $Pb^2V^2O^7 = 2PbO.V^2O^5$, analogous in composition to a pyrophosphate.

The metavanadates are mostly yellow; some of them however, especially those of the alkaline earth-metals, and of zinc, cadmium, and lead, are converted by warming—either in the solid state, or under water, or in aqueous solution, especially in presence of a free alkali or alkaline carbonate—into isomeric colourless salts. The same transformation takes place also, though more slowly, at ordinary temperatures. The metavanadates of alkali-metal are colourless. The acid vanadates are yellow, or yellowish-red, both in the solid state and in solution; hence the solution of a neutral vanadate becomes yellowish-red on addition of an acid. The metavanadates of known reducing agent, and bleaches indigo and other vegetable colours as quickly as chlorine. (Roscoe.)

---

* $3MO.VO^3$, according to the old atomic weights.

The degree of oxidation of the vanadium in the lavender-coloured solution was ascertained by oxidising it with a standard solution of permanganate. By this method it was found that 150 pts. of vanadium-pentoxide lost 26·53 per cent. oxygen on reduction with zinc; the calculated loss from V^2O^5 to V^2O^2 is 26·3.

When the neutral lavender-coloured solution of a hypovanadious salt is left exposed to the air for a few seconds, the colour changes to a deep chocolate-brown from absorption of oxygen; indeed, this reaction is as delicate as that of an alkaline pyrogallate. If air be passed through the acid lavender-coloured solution of hypovanadious sulphate, oxygen is absorbed, the liquid assumes a permanent blue colour, and the vanadium is then contained in solution as tetroxide. If the free acid contained in the lavender solution be neutralised by zinc, the liquid, on exposure to air, attains a permanent brown tint, which, on addition of acids, becomes green, the solution then containing vanadium-trioxide. (Roscoe.)

Vanadium-trioxide, V^2O^3, or **Vanadyl-monoxide,** $(V^2O^2)''O$. (Berzelius's suboxide).—Obtained by igniting the pentoxide in hydrogen-gas, or in a crucible lined with charcoal. It is a black powder, with an almost metallic lustre, and infusible; by pressure it may be united into a coherent mass which conducts electricity (Schafarik). When exposed warm to the air, it glows, absorbs oxygen, and is converted into pentoxide. At ordinary temperatures, it slowly absorbs oxygen, and is converted into tetroxide. By ignition in chlorine-gas it is converted into vanadyl-trichloride and vanadium-pentoxide. It is insoluble in acids, but may be obtained in solution by the reducing action of nascent hydrogen evolved from metallic magnesium on a solution of vanadic acid in sulphuric acid. 100 pts. of vanadium-pentoxide were found to lose, on reduction with magnesium, 17·7 per cent. oxygen; the calculated loss, on reduction to V^2O^3, is 17·5 per cent. Solutions of vanadium-trioxide may also be obtained by partial oxidation of the lavender-coloured solution of the dioxide (Roscoe). According to Schafarik, vanadium-trioxide unites with acids, forming salts (which may be called hypovanadic salts), red in the anhydrous, and green in the hydrated state. When the tetroxide or pentoxide is ignited in a glass-tube in a stream of hydrogen, the glass acquires a red colour, in consequence of the formation of hypovanadic silicate.

Vanadium-tetroxide, V^2O^4. *Vanadious Oxide* or *Anhydride*. (Berzelius's vanadic oxide.)—This oxide is produced, either by the oxidation of the dioxide or trioxide, or by the partial reduction of the pentoxide. By allowing the trioxide to absorb oxygen at ordinary temperatures, the tetroxide is obtained in blue shining crystals. It dissolves in acids, the more easily in proportion as it has been less strongly ignited, forming solutions of vanadious salts, which have a bright-blue colour. The same solutions are produced by the action of moderate reducing agents, such as sulphurous, sulphydric, or oxalic acid, upon vanadic acid in solution; also by passing air through acid solutions of the dioxide till a permanent blue colour is attained. 100 pts. of vanadium-pentoxide, reduced with sulphurous or sulphydric acid, lose 9·03 per cent.; the calculated loss on reduction to the tetroxide is 8·75 per cent. (Roscoe.)

The principal reactions of vanadious salts have been already mentioned (p. 985). The solutions treated with alkaline carbonates, yield a precipitate of vanadious hydrate, which, when dried out of contact with the air, is neutral, has a grey colour, and is insoluble in water. It oxidises readily in contact with the air, acquiring a brown colour and acid reaction, and imparting a green colour to water. It dissolves easily in acids, and, when ignited, leaves the anhydrous tetroxide.

Vanadious phosphate and sulphate have been obtained in definite crystals (iv. 586; v. 617).

Vanadium-tetroxide also unites with the more basic metallic oxides, forming salts called vanadites. Those of the alkali-metals are soluble in water, and are formed by dissolving the tetroxide or the corresponding hydrate in caustic alkalis; the rest are insoluble and are obtained by precipitation.—The *ammonium-salt* is likewise produced by adding ammonia to a warm solution of a vanadious salt (the sulphate, for example), till the resulting precipitate redissolves with black-brown colour. This solution, if left to itself in a well-closed vessel, deposits vanadite of ammonium on cooling, as a brown crystalline powder, the liquid then becoming colourless. The salt dissolves in pure water, forming a brown solution, from which it is precipitated by ammonia.—The *potassium-salt*, prepared in a similar manner, forms brown shining crystals.

The insoluble vanadites have been but little examined.—The *manganous salt* is a brown powder, which, when exposed to the air in the moist state, oxidises to manganous vanadate.—The *mercuric salt* is thrown down, together with chloride of dimercurammonium (white precipitate), on adding ammonia to a solution of mercuric chloride mixed with a vanadous salt. The precipitate, when ignited, leaves vanadium-tetroxide, still retaining a small quantity of mercuric oxide.

Vanadium-pentoxide, V^2O^5. *Vanadic Oxide. Vanadic Anhydride. Anhydrous Vanadic Acid.*—This is the highest oxide of vanadium. It is prepared by igniting vanadate of ammonium in an open platinum-crucible; when cold, it has a rusty-yellow colour, lighter in proportion as the oxide is more finely divided.—The pentoxide may also be obtained by dissolving the impure tetroxide in strong sulphuric acid, and evaporating the solution. Pure vanadic sulphate, $V^2O^5.2SO^3.H^2O$ (p. 617—there called "basic vanadic sulphate," and represented by the formula $VO^3.2SO^3$), then remains as a light, orange-coloured, sandy powder, which, on ignition, leaves the pure pentoxide (Fritzsche, J. pr. Chem. liii. 93).—Very pure vanadium-pentoxide is likewise obtained by decomposing vanadyl-trichloride with water (Schafarik):

$$2VOCl^3 + 3H^2O = V^2O^5 + 6HCl.$$

Pure vanadium-pentoxide has a more or less reddish-yellow colour: it is tasteless, reddens moistened litmus-paper, and dissolves in 1,000 pts. of water, forming a light-yellow solution. When heated, it melts without decomposition, if kept from contact with deoxidising substances; and the red liquid crystallises on cooling, becoming incandescent at the moment of solidification, in consequence of the heat then suddenly evolved. The solidified mass is yellowish-red, and according to Nordenskjold (Pogg. Ann. cxii. 160), contains more or less distinct rhombic crystals.

Vanadium-pentoxide is not altered by simple ignition, but is easily reduced by heating with potassium, charcoal, hydrogen, carburetted hydrogen, organic substances, &c. In solution, it is also easily reduced by sulphurous or sulphydric acid, and even by nitrous acid; also by stannous salts, and by sugar, alcohol, and other organic substances, the colour of the solution then changing from red or yellow to green and blue. The solution of the acid in hydrochloric acid gives off chlorine when evaporated; tincture of galls colours the solution of vanadic acid black, on standing, in consequence of reduction.

Vanadic Hydrate or *Vanadic Acid*, $H^2O.V^2O^5$ + aq. or $2HVO^3.H^2O$, is obtained, by treating a somewhat concentrated solution of an anhydrovanadate of alkali-metal with nitric acid, as a bulky flocculent precipitate, which dries up in the air to a light brown-red powder having the composition just mentioned. It gives off 1 at. water over oil of vitriol, and when dried by heat, forms solid lumps, having a conchoïdal fracture.

Vanadium-pentoxide dissolves in the stronger acids, forming red or yellow solutions, which are partly decolorised by boiling and evaporation, especially when they contain excess of vanadium; many of these solutions yield crystalline compounds by spontaneous evaporation. (See PHOSPHATOVANADIC ACID, iv. 686; and SULPHATES OF VANADIUM, v. 617). Alkalis added to the solutions, form precipitates soluble in excess. The solutions are easily reduced by oxidisable substances.

VANADATES.—Vanadium-pentoxide unites with bases much more readily than with acids. When fused with alkaline carbonates, it eliminates 3 at. carbonic anhydride, forming orthovanadates, analogous to the orthophosphates, *e.g.*:

$$3(Na^2O.CO^2) + V^2O^5 = 3Na^2O.V^2O^5 + 3CO^2.$$

It also forms metavanadates, analogous to the metaphosphates, and two series of acid vanadates or anhydrovanadates, viz.:

$$\begin{array}{llcl}
\text{Orthovanadates, } M^3VO^4 & = \left.\begin{matrix}(VO)'''\\ M^3\end{matrix}\right\}O^3 & = & 3M^2O.V^2O^5.^* \\
\text{Metavanadates, } MVO^3 & = \left.\begin{matrix}(VO)'''\\ M\end{matrix}\right\}O^2 & = & M^2O.V^2O^5. \\
\text{Divanadates, } M^2V^4O^{11} & = 2MVO^3.V^2O^5 & = & M^2O.2VO^5. \\
\text{Trivanadates, } M^2V^6O^{16} & = 2MVO^3.2V^2O^5 & = & M^2O.3V^2O^5.
\end{array}$$

Metavanadate of lead occurs native, as *Dechenite*; the orthovanadate also, combined with lead-chloride, as *Vanadinite*. *Descloizite* is a diplumbic vanadate, $Pb^2V^2O^7$ = $2PbO.V^2O^5$, analogous in composition to a pyrophosphate.

The metavanadates are mostly yellow; some of them however, especially those of the alkaline earth-metals, and of zinc, cadmium, and lead, are converted by warming —either in the solid state, or under water, or in aqueous solution, especially in presence of a free alkali or alkaline carbonate—into isomeric colourless salts. The same transformation takes place also, though more slowly, at ordinary temperatures. The metavanadates of alkali-metal are colourless. The acid vanadates are yellow, or yellowish-red, both in the solid state and in solution; hence the solution of a neutral vanadate becomes yellowish-red on addition of an acid. The metavanadates of ammonium, the alkali-metals, barium, and lead are but sparingly soluble in water, the other metavanadates are more soluble. The alkaline vanadates are more soluble in pure water than in water containing free alkali or salt; hence they are precipitated from their solution, by addition of alkali in excess, or of salts. The vanadates are insoluble in alcohol. The aqueous solutions of vanadates form yellow precipitates with *antimony-*, *copper-*, *lead-*, and *mercury*-salts; with *tincture of galls*, they form a deep black liquid.

---

* $3MO.VO^3$, according to the old atomic weights.

Vanadates containing fixed bases are not decomposed by ignition; strong *acids* turn their solutions red, and when added in excess, often throw down very acid salts. From concentrated solutions of acid vanadates, *nitric acid* throws down a bulky brown precipitate of vanadic acid, retaining a small quantity of the base.—*Hydrochloric acid* decomposes the vanadates, with evolution of chlorine and formation of vanadium-tetroxide.—*Acetic acid*, in excess, takes away part of the base from neutral vanadates, converting them into di- and tri-vanadates.—*Sulphurous acid*, *alcohol*, and other reducing agents, colour the acid solutions blue, by formation of vanadium-tetroxide.

The vanadates have been examined chiefly by **Berzelius**, and more recently by v. **Hauer** (J. pr. Chem. lxix. 385; lxxvi. 156, 929; lxxx. 324), and **Czudnowicz** (Pogg. Ann. cxx. 17; Jahresb. 1863, p. 221); their crystalline forms by **Grailich** (*Krystallographische Untersuchungen*, Wien u. Olmütz, 1858, p. 3).

Vanadates of Ammonium.—The *metavanadate*, $(NH^4)VO^3$, is obtained by adding an excess of ammonia to the reddish-yellow acid solution of vanadic acid in ammonia, then warming it and leaving it to evaporate, or mixing it with alcohol; also by placing a lump of sal-ammoniac, more than sufficient for saturation, in a solution of potassium- or sodium-vanadate (p. 985). It separates in colourless, transparent, crystalline crusts, which dissolve slowly in cold water, forming a colourless liquid; quickly in boiling water, forming a yellow solution. It is decomposed by heat, leaving vanadium-pentoxide when heated in contact with the air. Its solution forms, with tincture of galls, a deep black liquid, which may be used as an insoluble ink. Alkalis do not act upon it; acids colour it blue; chlorine destroys the black colour, but the ink does not fade spontaneously (**Berzelius**).—*Yellow metavanadate.*—The yellow solution of vanadic acid in ammonia mixed with excess of ammonia, and left to evaporate *without warming*, yields lemon-yellow indistinct crystals, which dissolve in water with the same colour, and are reprecipitated therefrom by alcohol.

The *divanadate*, $2(NH^4)VO^3.V^2O^5.4H^2O$ or $(NH^4)^2O.2V^2O^5.4H^2O$, is obtained by saturating warm aqueous ammonia with vanadic acid, and leaving it to evaporate; or by mixing a boiling solution of the metavanadate, gradually and with agitation, with acetic acid, till the precipitate redissolves. The yellowish-red liquid, on cooling, deposits the salt in large, transparent, orange-red crystals, which dissolve in water, and are precipitated by alcohol as a lemon-yellow powder.—This *trivanadate*, $(NH^4)VO^3.V^2O^5.3H^2O$ or $(NH^4)^2O.3V^2O^5.6H^2O$, is obtained by repeated crystallisation of the diacid salt from water containing acetic acid. It forms large splendid red crystals, which are permanent in the air, more soluble in water than the preceding salt, but give off water and ammonia at a moderate heat. (v. **Hauer**.)

Vanadates of Barium.—The *metavanadate*, $Ba''(VO^3)^2.H^2O$, is obtained, by double decomposition, as a yellow gelatinous precipitate, which turns white slowly in the cold, immediately when heated. The white and yellow salts, which have the same composition, dissolve sparingly in water, each with its own colour, and the solution, when left to evaporate, deposits the salt in white crystalline grains. It dissolves with red colour in strong sulphuric acid. When heated, it gives off water, and turns yellow, but becomes white again on cooling. At a red heat, it melts to a yellow-brown transparent mass. It is completely decomposed by fusion with acid sulphate of potassium.—The *divanadate*, $Ba''(VO^3)^2.V^2O^5$, separates by spontaneous evaporation, from a solution of potassium-divanadate mixed with chloride of barium, in orange-yellow prisms, or on addition of alcohol, in shining lemon-yellow scales, slightly soluble in water.—Another *acid salt*, $3BaO.5V^2O^5.19H^2O = 3Ba(VO^3)^2.2V^2O^5.19H^2O$, is obtained by dropping chloride of barium into a warm solution of the divanadate, and then adding acetic acid till the precipitate redissolves. The solution, on cooling, deposits the salt in reddish-yellow, shining, oblique prisms. (v. **Hauer**.)

A so-called *basic salt* (? the orthovanadate) is formed, on mixing the solution of the metavanadate with baryta-water, as a yellow precipitate, which after a while turns white.

Vanadates of Calcium.—The *metavanadate* is obtained, by slow evaporation of ammonium-vanadate mixed with calcium-chloride, in white or yellowish crystalline crusts; it is moderately soluble in water (more soluble than the strontium-salt), and is precipitated by alcohol.—The *acid salt* forms large, orange-red, non-efflorescent crystals, easily soluble in water.—A *basic salt* (? orthovanadate) is said to be obtained by mixing the solution of the metavanadate with lime-water.

Vanadates of Copper.—*Cupric metavanadate* separates, as a yellow precipitate, on adding alcohol to a mixture of a cupric salt and potassium-metavanadate.—An *acid salt* separates, as a yellow crystalline crust, from a solution of acid potassium-vanadate mixed with cupric sulphate.

Cupric orthovanadate occurs native in volborthite, a mineral found at Friedrichsrode in the Thuringian Forest, and at Syssersk and Nischne-Tagilsk in Russia. The mineral from Friedrichsrode contains, according to Credner's analysis (Pogg. Ann. lxxix. 546), 39·02 per cent. V^2O^5, 38·27 CuO, 16·62 CaO, and 5·05 water, together with 0·92 MgO, 0·52 MnO, and 0·76 insoluble matter, agreeing nearly with the formula $(Cu;Ca)^3(VO^4)^2.(Cu;Ca)H^2O^2$; that from Russia appears to be similarly constituted, but to contain only copper without calcium; but it has not been analysed. The specific gravity of the Thuringian mineral is 3·495; that of the Russian, 3·55. Hardness = 3. Both minerals form small six-sided tables, spherical, radiate, granulo-laminar or scaly lumps, or earthy deposits, having an olive-green, grass-green, siskin-green, or lemon-yellow colour, vitreous and nacreous lustre, and yellow or greenish-yellow to greyish streak. The mineral is soluble in nitric acid.

Vanadates of Lead.—The *metavanadate*, $Pb(VO^3)^2$, occurs native as dechenite (ii. 308). It is also obtained by precipitating either the metavanadate or acid vanadate of potassium with acetate of lead. It dissolves slightly with yellow colour in water, easily in dilute nitric acid; when it is heated with strong nitric acid, a brown substance separates, probably consisting of a lead-vanadate containing a very large excess of acid. The metavanadate is not decomposed by boiling with aqueous carbonate of potassium, and not completely by boiling with strong sulphuric acid; but fusion with acid sulphate of potassium decomposes it perfectly.—The *divanadate*, $Pb(VO^3)^2.V^2O^5$, is obtained by precipitating the acid potassium-salt with nitrate of lead, as an orange-yellow precipitate, slightly soluble, with yellow colour, in water.

A *diplumbic vanadate* (pyrovanadate), $Pb^2V^2O^7 = 2PbO.V^2O^5$, occurs native as descloizite.

The *triplumbic salt*, or *orthovanadate*, occurs native in combination with chloride of lead, as vanadinite or vanadite, $PbCl^2.3Pb^3VO^4$, a mineral occurring at Zimapan in Mexico, in the county of Wicklow in Ireland, at Wanlockhead in Scotland, at Windischkappel in Carinthia, and at Beresowsk in the Ural, in crystals belonging to the hexagonal system, isomorphous with pyromorphite and mimetesite. The crystals usually exhibit the combination of the hexagonal prism, ∞P with the basal face oP and the hexagonal pyramid P, having the angle P : P in the terminal edges = 143°. It also forms kidney-shaped lumps, with fusiform to fibrous separation. Colour yellow to brown. Lustre waxy to adamantine. Transparent to translucent on the edges only. Hardness = 3. Specific gravity = 6·8 to 7·2 It dissolves in nitric acid, forming a yellow solution, any undissolved portion becoming covered with a red deposit of vanadium-pentoxide.

Analyses:—*a*. From Zimapan (Berzelius).—*b*. From Wicklow in Ireland (Thomson, *Outlines*, i. 574).—*c*. From Windischkappel: crystallised; specific gravity = 6·886 (Rammelsberg, Pogg. Ann. xcviii. 249).—*d*. From Beresowsk: brown crusts on crystallised pyromorphite; specific gravity = 6·863 (Struve, Verh. d. min. Ges. zu Petersburg, 1857):

A *cupricoplumbic vanadate* called chileite, occurring as an amorphous brown substance in cavities of the massive pyromorphite of Mina Grande in Chile, was found by Domeyko (Ann. Min [4], xiv. 145) to contain 15·21 per cent. V^2O^5, 5·26 As^2O^5, 0·72 P^2O^5, 60·56 PbO, 17·88 CuO. and 0·37 $PbCl^2$, which may be represented, approximately, by the formula $(Pb;Cu)^3(VO^4)^2.3(Pb;Cu)O$, the vanadium being partly replaced by arsenic and phosphorus.

Vanadates of Lithium.—The *metavanadate* crystallises from concentrated solutions, in radiate groups of slender colourless needles, easily soluble in water.—The *acid salt* forms large red efflorescent crystals, resembling acid chromate of potassium, easily soluble in water and not completely precipitated by alcohol.

Vanadates of Potassium.—The *metavanadate*, KVO^3 or $K^2O.V^2O^5$, disolves slowly in cold, easily in boiling water, with difficulty in water containing potash. The solution yields, by spontaneous evaporation, a syrup which dries up to a white earthy mass, melting when heated to a transparent yellow liquid, and becoming white again on cooling.—The *acid salt*, $2KVO^3.V^2O^5.3H^2O$, or $K^2O.2V^2O^5.3H^2O$, is obtained by fusing the metavanadate with vanadium-pentoxide, or by boiling it with addition of water. It forms broad, reddish-yellow, crystalline laminæ, slightly soluble in cold, abundantly in boiling water. The crystals, when heated, give off their water, and turn brick-red; the dry salt is easily fusible, and forms a yellow mass on cooling. The salt is partially decomposed by boiling with a small quantity of water, metavanadate and divanadate dissolving, and a more acid salt remaining behind. On mixing a cold concentrated solution of the divanadate with caustic potash, the divanadate partly separates unaltered; but if the two solutions are mixed hot, metavanadate is produced.

Vanadates of Silver.—The *metavanadate* is a gelatinous, yellowish, or whitish precipitate, soluble in nitric acid and in very dilute ammonia, and precipitated from the latter solution by concentrated ammonia. It is not completely decomposed by hydrochloric acid.—The *acid salt* is yellowish-red, slightly soluble in water, easily soluble in nitric acid and in very dilute ammonia. It melts below a red heat, and crystallises on cooling. The ammoniacal solution yields, by evaporation, crystals of ammonio-argentic vanadate.

Vanadates of Sodium.—The *metavanadate* resembles the potassium-salt.—The *divanadate*, $2NaVO^3.V^2O^5.9H^2O = Na^2O.2V^2O^5.9H^2O$, is prepared like the corresponding potassium-salt, and separates, by spontaneous evaporation, in large crystals of a splendid orange-red colour. It is but slightly soluble in water, even at the boiling heat: nevertheless, 1 pt. of it imparts a distinct yellow colour to 200,000 pts. of water It effloresces in dry air, acquiring a rusty-brown colour, melts at an incipient red heat, and forms, on cooling, a shining, amorphous, varnish-like mass of a dark-red colour.

A *phosphatovanadate of sodium* is obtained by heating a mixture of vanadic and sodic phosphates with nitric acid.

Vanadates of Strontium.—The *metavanadate*, $Sr(VO^3)^2$, is gradually precipitated by chloride of strontium from metavanadate of ammonium, in white crystalline grains. It is more soluble than the barium-salt. The solution, mixed with strontia-water, forms, after some time, a yellow precipitate, which afterwards turns white (probably the orthovanadate).—The *divanadate*, $Sr(VO^3)^2.V^2O^5.9H^2O = SrO.2V^2O^5.9H^2O$, separates on cooling from a hot very strong solution of sodium-divanadate mixed with chloride of strontium, in shining orange-red crystals, having the form of sodium-divanadate. It is not very soluble in water, but more soluble than the barium-salt. The crystals do not effloresce even in dry air.—The *trivanadate*, $Sr(VO^3)^2.2V^2O^5.14H^2O = SrO.3V^2O^5.14H^2O$, is prepared by mixing a solution of an alkaline divanadate with acetic acid and strontium-chloride, and heating the liquid nearly to the boiling-point. A straw-yellow basic salt is then deposited, and the deep-red filtrate evaporated over oil of vitriol yields crystals of the trivanadate. By recrystallisation, with addition of a large quantity of free acetic acid, it is obtained pure, in large, red, diclinic crystals, exhibiting a golden-yellow surface-lustre by reflected light. They are permanent in the air, give off 8 at. water at 100°, turn yellow, and melt at a low red heat to a dark-red liquid which solidifies to a crystalline mass on cooling. The salt dissolves easily, and without decomposition, in water, on addition of acetic acid. (v. Hauer, J. pr. Chem. lxxvi. 156.)

Vanadates of Vanadium.—Several oxides of vanadium, intermediate in composition between the tetroxide and pentoxide, and perhaps consisting of compounds of the two, are described by Berzelius. They are produced by direct oxidation of the tetroxide, or by mixing vanadious salts with vanadates in various proportions. The compounds thus characterised are:—1. A purple oxide, formed when vanadious hydrate is left for twenty-four hours in a vessel not perfectly closed; 2. A green oxide containing $V^2O^2.2V^2O^5$; 3. A yellow-green oxide, $V^2O^2.4V^2O^5$; and 4. An orange-yellow oxide. (See Gmelin's *Handbook*, iv. 84.)

The remaining vanadates have not been examined with sufficient exactness to render special description necessary.

VANADIUM, OXYBROMIDE OF, or **VANADYL-BROMIDE**, $VOBr^3$.—This compound (regarded by Schafarik, who discovered it, as tribromide of vanadium, VBr^3), is formed, like the corresponding oxychloride, by igniting a mixture of vanadium-tetroxide and charcoal in bromine-vapour. It forms needle-shaped crystals, having a dark-brown colour and blue metallic iridescence. (Schafarik.)

VANADIUM, OXYCHLORIDES OF.—*a. Vanadium-oxytrichloride*, or *Vanadyl-trichloride*, $VOCl^3$ (usually regarded as vanadium-trichloride), is prepared: (*α*). By the action of chlorine on vanadium-trioxide:

$$3V^2O^3 + 6Cl^2 = V^2O^5 + 4VOCl^3.$$

(*β*.) By burning the dioxide (Berzelius's metal) in chlorine-gas, at a red heat, a greenish-yellow vapour being then formed, which condenses to a liquid.—(γ.) By passing chlorine-gas over an ignited mixture of the trioxide, tetroxide, or pentoxide of vanadium, with charcoal, and condensing the resulting vapours in a cooled U-tube. The liquid is freed from excess of chlorine by passing dry air through it, or by rectifying it over mercury.

Vanadyl-trichloride is a golden-yellow liquid, of specific gravity 1·764 at 20°, (Schafarik), 1·841 at 14·5° (Roscoe). Boiling-point 127°. Vapour-density = 6·41 (Schafarik), 6·108 (Roscoe); calc. (2 vols.) = 6·119. When exposed to the air, it emits cinnabar-coloured vapours, being resolved by the moisture of the air into hydrochloric and vanadic acids. With a small quantity of water, it becomes turbid, from separation of vanadic acid; with a larger quantity, it forms a clear pale-yellow solution, which when left to itself for some time, or more quickly when heated, gives off chlorine, turns green or blue, and then contains vanadium-tetrachloride, or the corresponding oxide, or vanadyl-dichloride. The same effects are produced on dissolving vanadyl-trichloride in hydrochloric acid. The recently prepared solution in hydrochloric acid dissolves gold. Vanadyl-trichloride dissolves also in alcohol, the solution, however, being quickly reduced to a lower chloride. (Schafarik.)

The following experiments show that this compound contains oxygen:—(1.) The vapour, passed over perfectly pure carbon at a red heat, yields carbonic anhydride.—(2.) It oxidises magnesium, converting it into magnesia.—(3.) It converts sodium into caustic soda.—(4.) Its vapour passed, together with hydrogen, through a red-hot tube, yields vanadium-trioxide. (Roscoe.)

β. *Vanadium-oxydichloride*, or *Vanadyl-dichloride*, $VOCl^2$.—This compound, obtained by the action of zinc on vanadyl-trichloride at 400° in sealed tubes, is a light-green crystalline solid, having a specific gravity of 2·88, insoluble in water, deliquescing on long exposure to the air, easily soluble in acids. (Roscoe.)

γ. *Vanadium-oxymonochloride*, or *Vanadyl-monochloride*, $VOCl$, formed by the action of hydrogen upon vanadyl-trichloride at a red heat, is a brown, light, powdery solid, insoluble in water, but easily soluble in acids. (Roscoe.)

δ. *Divanadyl-monochloride*, V^2O^2Cl, is also formed by the action of hydrogen at a red heat. It is easily separated from the preceding compound, as it is a heavy, shining, metallic powder, resembling mosaic gold. (Roscoe.)

VANADIUM, SULPHIDES OF. Two vanadium-sulphides are known, corresponding to the tetroxide and pentoxide.

The *tetrasulphide* or *Vanadious sulphide*, V^2S^4, is produced by heating the tetroxide to redness in a stream of sulphydric acid gas. It is black, very friable, of sp. gr. 4·70, insoluble in water, aqueous alkalis, and sulphides of alkali-metal, not altered by hydrochloric or sulphuric acid, but converted by nitric acid into vanadious sulphate. When heated in the air, it burns, producing sulphurous and vanadic anhydrides.

Hydrated vanadious sulphide is obtained by dissolving a vanadious salt in excess of an alkaline monosulphide, and precipitating with hydrochloric acid. The precipitate is brown at first, but becomes black, without decomposition, on washing and drying.

Vanadious sulphide unites with basic metallic sulphides, forming salts called sulphovanadites. Those of the alkali-metals are obtained by dissolving the hydrated sulphide in monosulphide of ammonium, &c., or by treating a vanadite with excess of sulphydric acid. These sulphosalts are black in the dry state, purple-brown in solution (like the permanganates). The other sulphovanadites are insoluble in water, and are obtained by precipitation. (Berzelius.)

Pentasulphide of Vanadium, or *Vanadic sulphide*, V^2S^5, cannot be formed in the dry way, but is obtained by dissolving the pentoxide, or an alkaline vanadate, in excess of alkaline monosulphide, and precipitating with hydrochloric acid. It is brown when moist, black in the dry state, but yields a brown powder. When heated in a retort, it is resolved in sulphur and the tetrasulphide; by heating in the air, it is oxidised to sulphurous and vanadic anhydrides. It dissolves, with red-brown colour, in aqueous solutions of alkaline carbonates, hydrates, and sulphydrates.

Vanadic sulphide unites with basic metallic sulphides, forming the sulphovanadates. Those of the alkali-metals are soluble in water, and are obtained by dissolving vanadium-pentoxide in excess of alkaline sulphide, or by treating the alkaline vanadates with excess of sulphydric acid; in the dry way also by fusing vanadium-compounds with alkali and sulphur.

The sulphovanadates of alkali-metal are brown in the dry state, red-brown in solution. The aqueous solution of the potassium-salt gives, with alcohol, a scarlet precipitate, which turns brown when washed with alcohol.—The sulphovanadates of barium, calcium, and strontium may be obtained as crystalline powders, slightly soluble in water. All the other sulphovanadates are insoluble in water, and are obtained by precipitation. (Berzelius.)

VANADYL. Syn. with VANADIUM-MONOXIDE (p. 987).

VANADYL-BROMIDE. See VANADIUM, OXYBROMIDE OF (p. 992).

VANADYL-DICHLORIDE. Syn. with VANADIUM-OXYCHLORIDE (p. 993).

VANADYL-TRICHLORIDE. Syn. with VANADIUM-OXYTRICHLORIDE (p. 992).

VANILLA. *Vanille. Vaniglia.*—The fruit of *Vanilla planifolia*, a climbing orchidaceous plant growing wild in Mexico, Brazil, and Guiana, and cultivated in Jamaica, Trinidad, Mauritius, Ceylon, Java, and other tropical countries. The pods, which are nearly cylindrical, five or six inches long, and a line or two thick, have a very pleasant aromatic taste and smell, and are often covered externally with white shining crystals of vanillin, which is their principal constituent. They also contain an iron-greening tannin, a non-drying fat-oil, wax, resin, &c.

Vanilla is used for flavouring ices, creams, chocolate, &c.; also in medicine in the form of powder and of alcoholic tincture.

VANILLIC ACID. Syn. with VANILLIN.

VANILLIN, $C^{10}H^6O^2$ (Gobley); $C^{17}H^{22}O^{15}$ (Stokkebye), the neutral odoriferous principle of vanilla, was formerly mistaken for benzoic, and afterwards for cinnamic acid. It was first recognised as a peculiar substance by Bley (Jahresb. 1858, p. 535; 1859, p. 508), further examined by Gobley (J. Pharm. [3], xxxiv. 401; Jahresb. 1858, p. 534), and afterwards by Stokkebye (Jahresb. 1864, p. 612), who designates it as *vanillic acid*.

Vanillin may be prepared by mixing the alcoholic extract of vanilla with water to a syrupy consistence; agitating with ether, evaporating, and treating the residue with boiling water; again evaporating; and treating the resulting crystals with animal charcoal (Gobley). It crystallises in long, colourless, four-sided prisms, bevelled at the ends. It is nearly insoluble in cold water, moderately soluble in hot water, more easily in alcohol, ether, and volatile oils. The alcoholic solution has a faint acid reaction. It melts at 76° (Gobley), at 82° (Stokkebye), begins to sublime at 150° (Gobley), and distils over with vapour of water (Stokkebye). It dissolves in strong sulphuric acid and in caustic potash. Nitric acid converts it into oxalic acid.

VAPOURS, DENSITY OF. See SPECIFIC GRAVITY (p. 365).

VAPOURS, LATENT HEAT OF. See HEAT (iii. 96).

VAPOUR, TENSION OF. See HEAT (iii. 81).

VAREC. The name applied in Normandy to the ash of seaweed, used as manure and for the preparation of bromine, iodine, and potassium-salts. In Scotland the same substance is called kelp (p. 210).

VARENNA-JUICE. *Succus varennæ.*—The juice of *Varenna polystacha*, a leguminous plant indigenous in Mexico. When dry, it has a brownish vitreous gloss, and consists almost wholly of tannin. (Soubeiran, J. Pharm. [3], xxviii. 196.)

VARIOLARIA. A genus of lichens, several species of which, viz. *V. dealbata*, *V. aspargilla*, *V. orcina*, and others, are used for the preparation of archil.—*V. amara* contains a bitter substance called picrolichenin (iv. 642).

VARIOLARIN. The name applied by Robiquet to a crystalline body, which he obtained from that portion of the alcoholic extract of *Variolaria dealbata* which is insoluble in water. It was probably lecanoric or orsellic acid.

VARIOLITE. A fine-grained to compact diorite, enclosing roundish lumps of felspar.

VARISCITE. A hydrated aluminic phosphate, occurring in quartz and silicious shale at Mosbach in the Saxon Voigtland. It contains small quantities of ferrous oxide, chromic oxide, magnesia, and ammonia, and is apparently related to turquois (iv. 551). It is non-crystalline, has an apple-green colour, and faint waxy lustre; hardness = 5·0 to 5·5. Specific gravity = 2·34 to 2·38. (A. Breithaupt, J. pr. Chem. x. 507.)

VARNISH. *Vernis. Firniss.*—A solution of a resinous substance spread over the surface of wood, metal, &c., and forming shining, transparent, hard crusts, capable of resisting the influence of air and moisture. The principal resins used for making varnishes are copal, animé, mastic, and sandarach; the solvents are spirits of wine, turpentine-oil, or linseed and other drying oils.

Crystal varnish for maps, prints, drawings, &c. is made by dissolving Canada balsam in the best oil of turpentine. (See *Ure's Dictionary of Arts and Manufactures*, iii. 940.)

VARVICITE. A manganese-ore from Warwickshire, consisting, according to Rammelsberg, of $MnO^2.Mn^2O^3.H^2O$; according to Phillips, of $MnO.3Mn^2O^3.H^2O$ (iii. 813).

VASCULOSE. A substance constituting, according to Frémy (Jahresb. 1859, p. 538), the principal part of the vessels of wood. It is distinguished by its insolubility in concentrated acids and in cuprate of ammonia, and is prepared by treating wood, first with dilute potash-ley, then repeatedly with hydrochloric acid, afterwards with cuprate of ammonia, and finally with cold hydric sulphate.

VATERIA. *V. indica*, a tree growing in Malabar, yields a semifluid resin, which hardens in the air, and is used for making Peynie-varnish.

VAUGNERITE. The name given by Fournet (Annal. des Minéral. [4], xix. 149) to a coarse-grained variety of diorite from the gneiss of Vaugneray (Départ. du Rhône), rich in oligoclase, blackish-green hornblende, and brown-black mica.

VAUQUELINE. A name originally given by Pelletier and Caventou to strychnine; also by Pallas to a crystalline substance obtained from the bark of the olive-tree.

VAUQUELINITE. Native chromate of lead and copper. (See CHROMATES, i. 934.)

VEGETABLE ALKALI. Syn. with POTASH (p. 700).

VEGETABLE ETHIOPS. A charcoal prepared by incinerating common seawrack (*Fucus vesiculosus*) in a covered crucible.

VEGETABLE IVORY. This name is applied to the tagua-nut, the fruit of *Phytelephas macrocarpa*, a tree growing on the borders of the Magdalen river in Columbia, South America. It contains about 80 per cent. of woody fibre, is very hard and compact, has the appearance of ivory, and may be turned in the lathe.

VEGETABLE PARCHMENT. See CELLULOSE (i. 819).

VEGETABLES, NUTRITION OF. See NUTRITION OF PLANTS (iv. 162).

VEIN-STONES. *Phlebolites.*—Concretions found in the veins, chiefly of the pelvis, and consisting of calcic phosphate and carbonate, with a small quantity of magnesia, and generally an organic nucleus.

The term *vein-stone* is also applied to the mineral substances which accompany and often enclose metallic ores.

VENETIAN CHALK. Syn. with STEATITE.

VENETIAN RED. A pigment formed of red hæmatite.

VENICE TURPENTINE. See TURPENTINE (p. 919).

VERANTIN. $C^{14}H^{10}O^5$? (Schunck, J. pr. Chem. lix. 474.)—A substance contained in madder-root, whence it is extracted by processes already described (pp. 121, 123). It is a reddish-brown amorphous powder, like snuff or roasted coffee. Boiling water scarcely dissolves it, but renders it soft and coherent. It is easily soluble in boiling alcohol; the solution reddens litmus. It dissolves in alkalis and alkaline carbonates, forming dingy-red solutions, from which it is precipitated in brown flocks by acids. The alcoholic solution forms dark-brown precipitates with cupric and plumbic acetates. Verantin also forms a stannous lake, the preparation of which is described under RUBIAFIN (p. 121). Verantin does not impart any colour to mordanted fabrics.

VERATRIC ACID. $C^9H^{10}O^4$.—An acid existing in sabadilla-seeds; discovered by E. Merck in 1839 (Ann. Ch. Pharm. xix. 180), further examined by Schrötter (*ibid.* xxix. 188), and by W. Merck (*ibid.* cviii. 58). It is prepared by exhausting sabadilla-seeds with alcohol acidulated with sulphuric acid, precipitating the extract with milk of lime, evaporating the filtrate, mixing the clear solution of calcic veratrate thus obtained with sulphuric or hydrochloric acid, and leaving it in a cold place. Veratric acid then crystallises out, and may be purified by solution in alcohol and treatment with animal charcoal.

Veratric acid crystallises from its alcoholic solution by spontaneous evaporation, in slender colourless spiculæ, or four-sided prisms. It has a slight acid reaction; dissolves sparingly in cold, more freely in boiling water; also in alcohol, especially when warm, but is insoluble in ether. At 100° the crystals give off water and become opaque; at a higher temperature they melt to a clear liquid, the acid afterwards subliming without decomposition.

Chlorine and *bromine* act strongly on veratric acid, forming viscid uncrystallisable substitution-products. The acid appears to be but slightly acted upon by *oil of vitriol*, and not at all by *pentachloride of phosphorus*. It dissolves in very strong *nitric acid*, and the solution, when mixed with water, deposits nitroveratric acid, $C^9H^9(NO^2)O^4$, which dissolves easily in alcohol, and crystallises therefrom in small yellow laminæ, melting and decomposing at 100°. This compound, boiled with nitric acid, is converted into dinitroveratric acid, which, however, is difficult to separate from the mononitrated acid. (W. Merck.)

Veratric acid distilled with excess of baryta is resolved into carbonic anhydride and veratrol: $C^9H^{10}O^4 = CO^2 + C^8H^{10}O^2$. (W. Merck.)

Veratric acid is monobasic.—The *veratrates of the alkali-metals* are crystallisable, non-deliquescent, easily soluble in water.—The *lead-salt* is insoluble.—The *silver-salt*, $C^9H^9AgO^4$, is a white precipitate, slightly soluble in water.

Ethylic Veratrate, $C^9H^9(C^2H^5)O^4$, is obtained by passing hydrochloric acid gas into a moderately concentrated solution of veratric acid in strong alcohol, distilling the saturated solution, treating the distillate with water, &c., as a radio-crystalline easily friable mass, having a specific gravity of 1·141 at 18°, inodorous, but having a slightly bitter, burning, and somewhat aromatic taste. It is slightly soluble in water, easily in alcohol, and separates therefrom by spontaneous evaporation in shining needles. It does not volatilise without decomposition; when heated in the air, it burns with a luminous flame. It is decomposed by heating with potash-ley. (Will, Ann. Ch. Pharm. xxxvii. 198.)

VERATRIN. Syn. with VERATRUM-RESIN (p. 997).

VERATRINE. $C^{32}H^{52}N^2O^8$. (Meissner, Neues Journ. v. Trommsdorff, v. 3. —Pelletier and Caventou, Ann. Ch. Phys. [2], xiv. 69.—Couerbe, *ibid.* lii. 352. —Merck, N. Journ. v. Trommsd. xxi. 134.—G. Merck, Ann. Ch. Pharm. xcv. 200.)—An organic base discovered, in 1818, by Meissner, in sabadilla-seeds (p. 141), and soon afterwards by Pelletier and Caventou, in white hellebore (*Veratrum album*); it is probably contained also in other species of veratrum.

Preparation.—1. The evaporated alcoholic extract of sabadilla-seeds is dissolved in dilute sulphuric acid; the solution treated with animal charcoal, and then precipitated by an alkali (100 pts. of the seeds, thus treated, yield 9 pts. veratrine); the precipitate still containing sabadilline and other bodies, is dissolved in dilute sulphuric acid, and nitric acid is added as long as a black pitchy precipitate is thereby produced; the filtrate is precipitated with dilute potash-ley; the washed and dried precipitate is dissolved in absolute alcohol; the solution evaporated; the residue boiled out with water, and the impure veratrine which remains is dissolved in ether, which, on evaporation, leaves the pure base (Couerbe).—2. The pulverised seeds are boiled with water containing hydrochloric acid; the extract is evaporated to a syrup; hydrochloric acid is added as long as it forms a precipitate; the filtered liquid is decomposed with excess of lime; the precipitate is treated with hot alcohol; the extract evaporated; the residue dissolved in dilute acetic acid, and precipitated by ammonia; and the precipitate is purified by ether. By this process, 5 kilogrammes of sabadilla-seeds yield 10 to 15 grammes of veratrine (Merck).—Delondre (J. Pharm. [3], xxvii. 417) prepares pure veratrine by exhausting crushed sabadilla-seeds with water containing hydrochloric acid in a displacement-apparatus, finally washing them with water, precipitating the extracts with a slight excess of potash, and heating the washed and dried precipitate with twice its weight of ether for four hours in a vessel which can be closed. The solution left to evaporate in shallow basins leaves pure veratrine.

Properties.—Veratrine is ordinarily a white or whitish-green crystalline powder; but, by spontaneous evaporation of its alcoholic solution, it is obtained in long prisms with rhombic base (Merck), which effloresce in contact with the air, assuming the aspect of porcelain, and becoming very friable (G. Merck). It is inodorous, but the smallest quantity introduced into the nose produces violent sneezing, accompanied by headache and general uneasiness. It is very acrid and poisonous, producing vomiting and purging when taken internally: 3 milligrammes of it killed a young cat in ten minutes. It is, however, used in medicine as an external application, and when taken internally, in properly regulated doses, is said to exert an antifebrile action. It is insoluble in water and alkaline liquids, very soluble in alcohol, and still more in ether (G. Merck). The solutions turn litmus blue.

Veratrine dried at 100° gives, by analysis, 64·51 to 65·00 per cent. carbon, 8·55 to 8·84 hydrogen, and 5·5 nitrogen (G. Merck). The formula $C^{32}H^{52}N^2O^8$ requires 64·86 C, 8·78 H, 4·73 N, and 21·63 O.

Veratrine melts easily when heated, and decomposes at a higher temperature; but by very careful heating, small quantities of pure veratrine may be sublimed without decomposition.

Strong *sulphuric acid* colours veratrine first yellow, then a fine carmine-red, and ultimately violet; according to Vasmer (Arch. Pharm. ii. 74), 1 pt. of veratrine imparts an amethyst-red colour to 3,000 pts. of the acid.—Strong *nitric acid* is coloured by veratrine, first scarlet, and then yellow.—Strong *hydrochloric acid* dissolves veratrine, especially when heated, forming a deep violet solution, and separating small drops of oily liquid.

Veratrine-salts.—Veratrine dissolves easily in dilute acids, forming colourless salts, which have a sharp burning taste and poisonous action. There appear to be two classes of veratrine-salts, inasmuch as Couerbe obtained crystallisable salts containing 2 at. hydrochloric or 1 at. sulphuric acid to 1 at. veratrine, whereas G. Merck obtained only uncrystallisable gummy salts containing half that proportion of acid.

The solutions of veratrine-salts are inactive to polarised light. Most of them give, with alkaline hydrates, carbonates, and phosphates, precipitates not perceptibly soluble in excess of the reagent. A solution of a veratrine-salt, mixed with tartaric acid, gives a precipitate with acid carbonate of sodium, but not with acid carbonate of potassium. The concentrated solutions give yellow precipitates with auric acid and platinic chloride, yellowish-white with potassium-iodide, light-red with potassium-sulphocyanate, kermes-brown with tincture of iodine, sulphur-yellow with picric acid. Tincture of galls renders the neutral solutions turbid, and on addition of hydrochloric acid, a copious white precipitate is formed.

Chloro-aurate of Veratrine, $C^{32}H^{52}N^2O^8.HCl.AuCl^3$, crystallises from solution in hot alcohol, on cooling, in thin yellow crystals having a silky lustre, and giving, by analysis, 20·87 to 21·26 per cent. gold (calc. = 21·09).

VERATROL. $C^8H^{10}O^2$. (W. Merck, *loc. cit.*)—A compound formed by distilling veratric acid (p. 997), with excess of baryta at a gentle heat. It is a colourless oil, having an agreeable aromatic odour, and specific gravity 1·086 at 15°, solidifying at + 15°, and boiling at 202°—205°.

Veratrol does not appear to unite with alkaline bisulphites. It is not altered by alkalis or by weak acids.—With *potassium* it forms a gelatinous mass without evolution of hydrogen.—*Chlorine* decomposes it, forming at first a crystalline product, converted by the further action of the chlorine into an unctuous mass.

Bromine converts veratrol into dibromoveratrol, $C^8H^8Br^2O^2$, which forms white prismatic crystals, insoluble in water, easily soluble in alcohol and ether, melting at 92°, and volatilising without decomposition at a higher temperature.

Nitric acid acts strongly on veratrol, forming at first nitroveratrol, $C^8H^9(NO^2)O^2$, which crystallises from alcohol in yellow laminæ. By further action of the nitric acid, dinitroveratrol, $C^8H^8(NO^2)^2O^2$, is produced, which forms long yellow needles, sparingly soluble in water, easily in alcohol, melting at 100°, and then volatilising with decomposition.

VERATRUM. *Rad. veratri*, the root of white hellebore (*V. album*), is used in medicine; it contains, according to Pelletier and Caventou, a volatile acid resembling sabadillic acid, also gallic acid and veratrine, together with starch, sugar, and fat; according to Simon, it contains also another base, called jervine (iii. 443).

Veratrum Sabadilla, Retz (*V. officinale*, Schlecht), yields sabadilla-seeds (*Semen sabadillæ*).

VERATRUM-RESIN. *Veratrin.* (Couerbe, Ann. Ch. Phys. [2], lii. 352.)—A constituent of sabadilla-seeds. When the solution decanted from the pitchy precipitate obtained in the preparation of veratrin after treatment with nitric acid (p. 996), is precipitated with potash, and the alcoholic solution of the resulting precipitate is evaporated, there remains a yellow resinous mass; and on exhausting this mass, first with water and then with ether, veratrum-resin remains behind, and may be purified by solution in alcohol and evaporation. This resin is said to have the composition $C^{14}H^{36}N^2O^3$, but it is perhaps only a mixture. It is brown, insoluble in water, ether, and alkalis, melts at 185°, and decomposes at a higher temperature. It unites with acids, but without neutralising them or forming crystalline compounds.

VERBASCUM. The flowers of great mullein (*V. Thapsus*), which are used in medicine as *flores verbasci*, contain, according to Morin, a resinous colouring-matter, volatile and fat oil, together with other constituents; according to Rossignon, the entire plant contains a large quantity of ammonium-nitrate.

VERBENA-OIL, from *Aloysia citriodora*, has a red colour, and yields, by distillation, an oxygenated oil, while the residual resinised portion gives off sulphydric acid when heated (Gladstone, Chem. Soc. J. xvii. 1). Respecting its specific gravity and optical properties, see OILS, VOLATILE (iv. 186).

VERDIGRIS. Basic cupric acetate. See ACETATES OF COPPER (i. 14).

VERDITER. The commercial name of normal cupric acetate, $Cu''(C^2H^3O^2)^2$ (i. 14).

VERMICULITE. A chloritic mineral from Vermont in North America, containing, according to Thomson (*Outlines of Mineralogy*, i. 372), 49·08 per cent. silica, 7·28 alumina, 16·96 magnesia, 16·12 ferrous oxide, and 10·27 water. It resembles scaly talc, but is specially characterised by swelling up very strongly before the blowpipe, and breaking out into vermicular excrescences before it melts. Similar minerals are found at Milbury in Massachusetts and at Westchester in Pennsylvania. (Handw. d. Chem. ix. 214).

VERMILLION. See Mercuric Sulphide (iii. 913).

VERMONTITE. The name of one of the five varieties (poisonous pyrites, mispickel, vermontite, dalarnite, and aconitite) into which A. Breithaupt divides the mineral species, arsenical pyrites, on account of differences in the angles.

VERNONIA. The seed of *V. anthelmintica* is known in commerce as *Calagero.*

VERTIDINE. An organic base, not yet isolated, existing, according to C. Gr. Williams (Chem. Soc. Qu. J. vii. 97), in very small quantity, in the tar of bituminous shale. On separating the volatile bases from the tar by the action of an acid, and subjecting them to fractional distillation, vertidine is found in the portion boiling between 183° and 210°. It imparts a fine green colour to solution of chloride of lime.

VESUVIAN. *Idocrase. Egeran. Gökumite. Loboite. Frugardite. Protheite. Wiluite. Cyprine. Xanthite.*—A calcio-aluminic silicate, $9(2CaO.SiO^2).2(2Al^2O^3.3SiO^2)$, in which the lime is replaced to a small amount by magnesia, ferrous oxide, and manganous oxide, and the alumina to a somewhat greater extent by ferric oxide. For analyses and discussion of formulæ, see Rammelsberg's *Mineralchemie* (pp. 734–739).

Vesuvian occurs in quadratic crystals, usually exhibiting the combination $P \,.\, oP \,.\, \infty P \,.\, P\infty \,.\, \infty P\infty$, &c. [somewhat like *fig.* 322 (Crystallography, ii. 160), supposing the terminal summits very much truncated]. Sometimes crystals occur with a great number of secondary faces. For P, the length of the principal axis is 0·4596. Angle P : P in the terminal edges = 129° 21′; in the lateral edges = 74° 27′. Cleavage indistinct parallel to ∞P and $\infty P\infty$. The crystals usually have the prismatic faces, more rarely the pyramidal faces predominant; they occur implanted and imbedded, intergrown, and forming aggregations of various character, from columnar or fibrous to granular, passing into massive. Fracture conchoïdal or uneven to splintery. Brittle. Hardness = 6 to 7. Specific gravity = 3·2 to 3·5. Colour brown or green, light or dark to nearly black; also yellow, rarely blue. Streak white. Lustre vitreous, sometimes very strong on the crystalline faces; also waxy, especially on the fractured surfaces. Transparent to translucent on the edges only. Before the blowpipe, vesuvian melts easily, and with intumescence, to a yellowish-green or brown glass; with borax or phosphorus-salt it exhibits the iron reaction, and with the latter a skeleton of silica. In its natural state it dissolves but imperfectly in hydrochloric acid; but after fusion it dissolves completely, with separation of gelatinous silica.

Vesuvian was first observed in the ancient Vesuvian lavas; it has since been found in serpentine, gneiss, and granular limestone. The mineral from Vesuvius has a hair-brown or olive-green colour; the crystals from Ala in the Val di Brozzo, in Piedmont, are usually transparent and shining, with a green or brown colour, rarely black. Egg near Christiania in Norway, the Ural, the Wilui river, near Lake Baikal, Cziklowa in the Bannat, and Monzoni in the Fassa valley, are other localities. Sulphur-yellow crystals have been found at Monzoni. A light-brown variety occurs in Donegal, Ireland. The variety called *frugardite* comes from Frugard in Finland; *gökumite*, or *loboite* from Gökum near Dannemora in Sweden. Liver-brown diverging crystals, from Eger in Bohemia, have been called *egeran*. Crystals called *cyprine*, of a blue tint, attributed to copper, come from near Tellemark in Norway; *xanthite* is from near Amity, New York. Vesuvian is found also at many other localities in the United States. (Dana, ii. 199.)

VETCH. See Vicia.

VETIVER. *Kus-kus. Iwarancusa-root.*—The rootstock of an Indian grass, probably *Anatherum muricatum*, and similar species, such as *Andropogon Schænanthus*, &c. It is used in India for making mats, for window-blinds and other coverings, these objects, when moistened with water, exhaling the fragrant odour of the vetiver-root. The root contains two essential oils, the more volatile of which is lighter than water, the other of more viscid consistence. 100 lbs. of root of good quality yield about ⅛ lb. of volatile oil resembling oil of sandalwood.

Citronella-oil, from the leaves of *Andropogon Schænanthus*, consists almost wholly of an oxygenated oil, boiling at 200°, and of specific gravity 0·8741 at 20°. Lemon-grass oil, from *Andropogon Nardus*, is scarcely distinguishable from citronella-oil. (Gladstone, Chem. Soc. J. xvii. 1.)

VIBURNIC ACID. See the next article.

VIBURNUM. A genus of trees and shrubs belonging to the caprifoliaceous order. The bark and berries of the guelder-rose (*V. opulus*) contain valeric acid (viburnic acid). The red berries of the wayfaring-tree (*V. Lantana*), contain, according to Enz (Jahresb. 1863, p. 614), an iron-greening tannic acid, valeric, acetic, and tartaric acids, a bitter principle, an acrid principle, red colouring-matter, sugar, gum, fat-oil, wax, resin, and chlorophyll.

VICIA. *Vetch.*—The seed of the common vetch (*Vicia sativa*) contains the ordinary constituents of leguminous seeds. According to Göbel, 100 pts. of the seeds contain 39 pts. starch and 4 pts. gluten. Greif found 68 pts. starch to 2 pts. gluten, besides sugar, albumin, &c.

The following table exhibits the composition of the ash of three species of vetch. I.—III. Seed of *V. sativa*.—I. according to Sprengel (J. techn. Chem. x. 350).—II. according to Lewi (Ann. Ch. Pharm. l. 421).—III. Vetch from Neufchatel (Cohen, *ibid.* lxxxv. 288).—IV. Straw of *V. sativa*. The air-dried straw contained 10—12 per cent. water, 26·0 substances extractable by water, 30·7 extractable by potash-ley, 42·0 woody fibre, and 5·10 ash (Sprengel, J. techn. Chem. vi. 398).—V. Ash of the entire plant of *V. sativa*. 100 pts. of the fresh plant yielded 82·9 pts. water and 1·1 ash. 1,000 pts. of the dry plant contained 2·38 pts. sulphur (Way and Ogston, Jahresb. 1858, p. 661, Table B).—VI. The tufted vetch (*V. cracca*): the entire plant yielded 68 per cent. water, 11·5 substances soluble in water, 13·8 substances soluble in dilute potash, and 1·626 ash (Sprengel, J. techn. Chem. viii. 355).—7. *Vicia dumetorum* contains, in the flowering state, 68·0 per cent. water, 10·4 substances soluble in water, 11·5 substances soluble in dilute potash-ley, and 2·25 ash (Sprengel, *loc. cit.*):

Ash of Vetches.

	Vicia sativa.					*V. cracca.*	*V. dumetorum.*
	Seed. I.	Seed. II.	Seed. III.	Straw. IV.	Entire plant. V.	Entire plant. VI.	Entire plant. VII.
Quantity of ash . .	2·29	2·40	5·10	2·6	6·50	1·62	2·25
Potash . . .	39·1	30·3	35·5	24·7	32·8	17·6	16·4
Soda	27·1	9·8	. .	13·1	. .	. .	3·0
Lime	7·0	4·7	38·3	8·0	20·7	52·5	55·3
Magnesia . . .	6·2	8·4	6·3	4·8	5·3	8·9	4·3
Ferric oxide . .	0·4	0·7	0·2	0·8	0·6	0·7	
Phosphoric anhydride	6·0	37·8	5·5	29·6	10·6	10·2	7·9
Sulphuric "	2·2	4·1	2·4	9·7	2·5	4·2	5·5
Silica . . .	8·7	2·0	8·7	1·1	1·3	2·9	3·8
Chlorine . . .	1·9	. .	. .	. .	. .	2·2	3·1
Alumina . . .	1·0	. .	0·3				
Manganic oxide . .	0·2	. .	0·1	trace	. .	. .	0·5
Chloride of sodium .	. .	2·0	2·6	7·5	7·3		

According to Schwerz, a hectare yields, on the average, 1,275 kilos. of seed of *Vicia sativa* (15 hectolitres), and 3,000 kilos. straw. The seed contains about 30·6 kilos., the straw 153·1 kilos., the entire plant, therefore, 183·7 kilos. of ash-constituents.

VIGNITE. A mineral from the Jura limestone near Vignes, in the Department of Moselle in France, consisting of greenish-blue grains, bound together by a cement of the same colour but different composition. The grains have a specific gravity of 3·7, and contain, according to Karsten (Archiv. f. Bergbau, xvi. 30), 41·12 per cent. ferric oxide, 29·98 ferrous oxide, 11·87 carbonic anhydride, 3·38 phosphoric anhydride, and 2·9 water, with small quantities of silica, alumina, magnesia, and lime; probably a decomposed iron-ore.

VILLARSITE. A hydrated magnesium-silicate, $4Mg^2SiO^4.H^2O$, with small quantities of iron, manganese, calcium, and potassium, occurring massive, and in granular aggregates, at Traversella in Piedmont. (Dufrênoy, Ann. Min. [4], i. 387.)

VINE. Boussingault (Ann. Ch. Phys. [3], xxx. 389) has determined the quantities of mineral constituents abstracted from the soil by the culture of the vine. As the leaves are returned to the soil, the products actually removed from the vineyard are limited to the wine, the lees, and the branches cut off in pruning. A vineyard of 170 acres, in Alsace, produced, in 1848, 65·05 hectolitres of wine, containing 10·294 kilos. of ash (1·87 grm. per litre); together with 492 kilos. of air-dried lees, containing 6·65 per cent. or 32·72 kilos. of ash; and, finally, 2,624 kilos. of branches, with 2·44 per cent. or 64·03 kilos. of ash. The composition of these ashes was as follows:

Ash of	K_2O.	Na_2O.	CaO.	MgO.	Fe_2O_3 and Al_2O_3.	SO_3.	Cl_2.	CO_2	P_2O_5.	Sand.	
Wine (1 litre)	0·842	—	0·092	0·172	—	0·096	trace	0·250	0·412	0·006	= 1·870
Lees .	36·9	0·4	10·7	2·2	3·4	5·4	0·4	12·4	10·7	15·3	= 97·8
Branches	18·0	0·2	27·3	6·1	3·8	1·6	0·1	20·3	10·4	10·9	= 98·7

The following table exhibits the quantities of the several mineral constituents removed by the vine-culture from the 170 acres of soil (as calculated from the preceding results,) compared with those removed by other crops grown on equal surfaces of land in the neighbourhood of the vineyard:

Abstracted by	K_2O.	Na_2O.	CaO.	MgO.	P_2O_5.	SO_3.
Wine	11·53	0·13	17·48	3·91	6·66	1·02
Lees	12·07	0·13	3·50	0·72	3·50	1·77
Branches	4·64	. .	0·51	0·95	2·27	0·53
Total . .	28·24	0·26	21·49	5·58	12·43	3·32
Potatoes	107·1		. .	. .	23·8	
Mangold-wurzel . . .	153·0		. .	. .	20·4	
Wheat, with straw . .	45·9		. .	. .	323·0	

Hence it appears that the culture of the vine does not remove more potash from the soil than that of cereals and root-crops.

On the composition of the several parts of the vine, see Crasso (Ann. Ch. Pharm. lvii. 69; lxii. 59; Jahresb. 1847–1848, p. 1082; Table B. Nos. 45–53).—On the ash of the several parts, also Berthier (Ann. Ch. Phys. [3], xxxiii. 249; Jahresb. 1851, p. 708).

In the juice exuding in spring from fresh-cut surfaces of the vine, Wittstein (Jahresb. 1857, p. 520), found chiefly potash, combined with citric and lactic acids; malic acid was not present.

VINETIN (from *vinetier*, the French name of *Berberis vulgaris*). The name given by Wacker to the base obtained by Polex from the root-bark of the common barberry, and by him called oxyacanthin (iv. 288). This latter name has also been given by Leroy to another base extracted from the white thorn (*Cratægus oxyacantha*).

VINEGAR. See Acetic Acid (i. 7).

VIOLA. The fragrant flowers of the violet (*V. odorata*) are said to contain, besides colouring-matter, slight traces of a volatile oil, two acids, one red and the other colourless, an emetic principle called violin (probably identical with emetin from ipecacuanha-root) (ii. 485), sugar, and other substances. The colouring-matter of the flowers is easily turned red by acids, and green by alkalis. The colourless acid called violenic acid by Peretti (Buchn. Repert. xl. 130), is said to crystallise in silky needles, to be soluble in water, alcohol, and ether, and to form yellow salts which stain the skin.

Viola tricolor (heartsease or pansy) contains a yellow colouring-matter, resin, vegetable mucus, and other substances, but no violin. (Boullay.)

VIOLA-EMETIN. Syn. with Violin (p. 1001).

VIOLAN. A silicate of aluminium, calcium, magnesium, and sodium, containing also iron and manganese, from St. Marcel in Piedmont. It occurs massive, and in indistinct, elongated, granular concretions, cleavable in two directions inclined at nearly 90°. It is nearly opaque, with a dark violet-blue colour, and vitreous lustre; hardness = 5 to 6; specific gravity = 3·233. (Plattner, J. pr. Chem. xv. 329.)

VIOLANTIN. $C^8N^6H^6O^9$. (Baeyer, Ann. Ch. Pharm. cxxvii. 223.)—A compound containing the elements of violuric and dilituric acids, and produced by their direct combination, just as alloxantin is formed from alloxan and dialuric acid:

$$\underset{\text{Violuric acid.}}{C^4N^3H^3O^4} + \underset{\text{Dilituric acid.}}{C^4N^3H^3O^5} = \underset{\text{Violantin.}}{C^8N^6H^6O^9}.$$

A mixture of the hot concentrated solutions of the two acids deposits violantin on cooling, in crystals containing $C^8N^6H^6O^9.4H^2O$. Violantin is likewise always produced by imperfect oxidation of violuric acid, or by imperfect reduction of dilituric acid. It may also be prepared by gently heating hydurilic acid with dilute nitric acid (the vessel being dipped into hot water), till a yellow colouring appears on the edges; on removing it, a brisk reaction sets in, and violantin separates as a yellowish-white crystalline body. If too little heat has been applied, the product is chiefly violuric acid; if, on the other hand, the mixture has been too strongly heated, dilituric acid is the principal product.

Violantin dissolves in *water*, but is resolved at the same time into violuric and dilituric acids. The same decomposition takes place on heating it with solutions of salts of the stronger acids, a diliturate of the base being then separated, and violuric acid remaining in solution. On heating it with *acetates*, both diliturate and violurate of the base are produced, the less soluble diliturate separating out, but in most cases strongly coloured by adhering violurate. From a mixture of equal parts of alcohol and water, violantin may be partly crystallised without decomposition.—*Ammonia-gas* colours violantin blue; aqueous ammonia decomposes it into violurate and diliturate.—*Sulphydric* and *hydriodic acid* easily reduce violantin to uramil.

Dry violantin heated to 120°, decomposes immediately through the entire mass, giving off gas, and leaving a brown substance which dissolves with red colour in caustic potash.

VIOLENIC ACID. See VIOLA (p. 1000).

VIOLET (ANILINE). *Hofmann's violet* consists of triethylrosaniline (iv. 471). According to Duprey (Bull. Soc. Chim. 1867, i. 95), it may be rendered soluble in water by decomposing the hydriodate with boiling caustic soda, and redissolving in an acid. Poirrier and Chappat (*ibid.* 1866, ii. 502) describe methods of preparing violet dyes from methyl-, ethyl-, and amyl-aniline, without first preparing rosaniline. Lauth (*ibid.* 362) prepares methylaniline-violet by simply heating certain salts of methylaniline. Thus, when a mixture of 10 pts. methylaniline, 3 pts. hydrochloric acid, and 200 pts. sand, is heated to 100°—220°, and the crude product exhausted with water, a solution is obtained having a very deep and pure violet colour. The colouring-matter contained in it may be purified from a trace of tarry matter, by precipitating with an alkali or alkaline salt, and redissolving the precipitate in water. A second precipitation yields the methylaniline-violet quite pure, and in the form of a fine green mass, which constitutes the commercial product. A similar product is obtained by subjecting methylaniline to the action of powerful oxidising agents, such as cupric nitrate, mercuric acetate, &c.

VIOLIN, or **VIOLA-EMETIN.** An emetic substance contained, according to Boullay, in all parts of the common violet. It has not been obtained pure, and is, perhaps, identical with emetin from ipecacuanha-root.

VIOLINE. This name was given by Price (Rep. of Patent Inventions, Feb. 1860), to a blue precipitate obtained by treating aniline with sulphuric acid and peroxide of lead.

VIOLURIC ACID, $C^4N^3H^3O^4$, or *Nitrosobarbituric acid*, $C^4N^2H^3(NO)^2O^3$. (Baeyer, Ann. Ch. Pharm. cxxvii. 200.)—An acid produced:—1. By the action of nitric acid, nitrous acid, or a metallic nitrite on hydurilic acid:

$$\underset{\text{Hydurilic acid.}}{C^8N^4H^6O^6} + HNO^3 = \underset{\text{Violuric acid.}}{C^4N^3H^3O^4} + \underset{\text{Alloxan.}}{C^4N^2H^2O^4} + H^2O.$$

$$\underset{\text{Hydurilic acid.}}{C^8N^4H^6O^6} + KNO^2 + 2HNO^2 = \underset{\text{Violurate of potassium.}}{C^4N^3H^2KO^4} + \underset{\text{Alloxan.}}{C^4N^2H^2O^4} + 2H^2O + N^2O^2.$$

2. Together with other substances, by the partial reduction of dilituric acid, ($C^4N^3H^3O^5$), as when that compound is cautiously heated with glycerin, or when ferrous diliturate is reduced by solution of potassium-cyanide.

To prepare it, hydurilic acid is warmed with water and nitrate of potassium, whereby deep-blue violurate of potassium is formed, the quantity of which may be increased by alternately adding small quantities of acetic acid (to neutralise free potash, which would exert a decomposing action) and nitrate of potassium. After filtering off the mother-liquor, the violurate of potassium is washed with a small quantity of water, mixed in hot solution with chloride of barium, and the precipitated violurate of barium is exactly decomposed by dilute sulphuric acid. The filtrate evaporated at 60°—70°, yields pure violuric acid (about ⅗ of the hydurilic acid used).

Violuric acid crystallises in shining, yellowish, rhombic octahedrons, containing $C^4N^3H^3O^4.H^2O$. They give off their water of crystallisation at 100°, dissolve with moderate facility in cold, more easily in hot water; the solution is not precipitated by alcohol.

Violuric acid soon turns mouldy in aqueous solution, and decomposes at the boiling heat; the dry acid likewise decomposes when strongly heated, giving off red fumes.—*Nitric acid* converts it into dilituric (nitrobarbituric) acid.—*Bromine* converts it, in aqueous solution, into alloxan-bromide or dibromobarbituric acid, and hydrobromic acid, with evolution of red vapours:

$$\underset{\text{Violuric acid.}}{2C^4N^2H^3(NO)O^3} + 4Br^2 + H^2O = \underset{\text{Dibromobarbituric acid.}}{2C^4N^2H^2Br^2O^3} + 4HBr + N^2O^3.$$

Heated with *chloride of lime*, it yields chloropicrin.—Heated with *caustic potash-ley*, it gives off a small quantity of ammonia, and is converted into hydrovioluric acid, a compound not yet examined.—Violuric acid heated with *soda-lime*, gives off all its nitrogen in the form of ammonia.

Reducing agents, such as *sulphydric, hydriodic acid*, &c., convert violuric acid into uramil (amidobarbituric acid):

$$\underset{\text{Violuric acid.}}{C^4N^2H^3(NO)O^3} + 2H^2S = \underset{\text{Uramil.}}{C^4N^2H^3(NH^2)O^3} + S^2 + H^2O.$$

With *sulphite of ammonium*, it forms sulphuric acid and thionurate of ammonium.—With *dilituric acid* it unites directly, forming violantin.

Violurates.—Violuric acid is monobasic. It decomposes acetates, but not chlorides. Its salts are distinguished by the great beauty and variety of their colours.

Violurate of Ammonium, $C^4N^3H^2(NH^4)O^4$, crystallises in fine, dark-blue, anhydrous prisms.—The *potassium-salt*, $C^4N^3H^2KO^4.2H^2O$, forms deep-blue laminæ or prisms, which dissolve in hot more easily than in cold water, forming a deep-blue solution. At 115°—120°, the salt gives off its water, and becomes greenish-blue. The solution mixed with excess of potash, turns red, perhaps from formation of a basic salt. A solution of potassium-violurate in hot concentrated hydrochloric acid deposits, on cooling, the compound $2(KCl.C^4N^3H^3O^4).HCl.6H^2O$, in large, colourless, shining, efflorescent prisms, easily soluble in water, sparingly in alcohol. At 100°, these crystals give off water and hydrochloric acid, leaving the compound $KCl.C^4N^3H^3O^4$.—*Violurate of sodium* forms red nodules composed of short needles, easily soluble in hot water.

Violurate of barium, $C^8N^6H^4Ba''O^8.4H^2O$, is precipitated by chloride of barium from a solution of the potassium-salt, in red shining quadratic tables, which are nearly insoluble in cold water, and give off all their water of crystallisation at about 230°.—The *calcium-salt* forms brick-red crystals.—The *cupric salt* is an amorphous olive-green precipitate.—*Ferrous salt.* Violuric acid added to ferrous acetate forms a dark-blue solution, from which alcohol precipitates ferrous violurate in six-sided tables with red metallic lustre; they dissolve easily in water, forming a dark-blue solution.—The *lead-salt*, $C^8H^4Pb''N^6O^8.4H^2O$, is obtained, by double decomposition, in small red crystals, becoming dark-red when dry. A reddish basic salt (containing 68 per cent. lead, and 0·5 hydrogen), is formed by precipitating the potassium-salt with basic acetate of lead.—The *magnesium-salt*, $C^8H^4Mg''N^6O^8.6H^2O$, separates, on cooling, from a warm mixture of magnesium-acetate and violuric acid or the potassium-salt, in hard, shining, purple-red, rhombic cystals, becoming dark-red when dry.—The *silver-salt* is a violet gelatinous precipitate.

VIRGINIA CREEPER. *Ampelopsis hederacea. Vitis hederacea*, L. *Hedera quinquifoliæ*, Du Roi.—The leaves of this plant, which turn red in autumn, contain a red colouring-matter, called by Wittstein cissotannic acid, which may be extracted by alcohol. 100 pts. of the fresh leaves yielded 1·56 per cent. ash, containing in 100 pts.: 23·9 K^2O, 12·0 Na^2O, 20·2 CaO, 8·0 MgO, 0·1 Al^2O^3, 0·6 Fe^2O^3, 3·1 SO^3, 15·1 P^2O^5, 5·0 SiO^2, 10·0 CO^2, and 1·8 Cl (Wittstein, Buchn. Repert. xcvi. 318).—The berries contain malic, tartaric, and citric acids (Riegel, Arch. Pharm. [2], lv. 153.)

VIRGINIC ACID. An acid obtained, according to Quevenne (J. Pharm. xxii. 449), by heating the fat-oil of the Virginian senega-root to 200°. It is described as a reddish-yellow oil, having a strong odour and sharp taste, soluble in alcohol, ether, and alkalis.

VIRIDE ÆRIS. Syn. with VERDIGRIS.

VIRIDIC ACID. $C^{14}H^{14}O^8$ (?) (Rochleder, Ann. Ch. Pharm. lxiii. 193.)—An acid produced by the oxidation of caffetannic acid in presence of ammonia. Coffee-beans owe their green colour to a small quantity of calcic viridate. To prepare the acid, the solution obtained by decomposing caffetannate of lead (i. 709) with sulphydric acid is supersaturated with ammonia, and left in contact with the air for thirty-six hours, till it acquires a deep-blue colour; then mixed with excess of acetic acid, which colours it brown; then with alcohol, which precipitates a few black flocks (of ulmous substance). The liquid filtered from these flocks is precipitated with acetate of lead, and the blue precipitate of lead-viridate is decomposed by sulphydric acid. The brown solution thereby obtained leaves viridic acid, on evaporation, as an amorphous mass of the same colour, and very soluble in water. The solution forms a blue precipitate with acetate of lead, greenish-blue with baryta-water, and is instantly coloured deep-green by ammonia, potash, or soda. Viridic acid dissolves in strong sulphuric acid, forming a solution of a fine crimson colour, from which water throws down a blue flocculent precipitate.

VIRIDIN. Syn with CHLOROPHYLL.

VIRIDINE. $C^{12}H^{19}N$.—A base obtained from coal-tar. Specific gravity = 1·017. Boiling-point 230°. Slightly soluble in water, easily in alcohol and ether.—The *platinum-salt*, $2(C^{12}H^{19}N.HCl)PtCl^4$, is greenish-brown, insoluble in alcohol and in ether.—The *mercuric salt* crystallises from water, and melts at 35°. (Thenius, Jahresb. 1861, p. 503.)

VIROLA TALLOW. The fat of *Virola sebifera*, Aubl. (*Myristica sebifera*, L.), a tree indigenous in Carolina and Guiana. It is obtained by boiling the shelled and bruised almonds with water; has a yellowish colour, melts at 40°—50°, dissolves in alcohol and ether, partly also in ammonia, and is slowly but completely saponified by potash. (Bonastre, J. Pharm. xix. 186.)

VISCAUTSCHIN. The portion of crude viscin which is insoluble in alcohol and ether, and, according to Reinsch, forms the chief constituent of bird-lime (i. 589).

VISCENE. An oil obtained by the dry distillation of viscin.

VISCIC ACID. See the next article.

VISCIN. A substance which forms the glutinous constituent of the stalks, leaves, and especially the berries of the mistletoe (*Viscum album*), and is the principal constituent of bird-lime. It is also contained in the receptacle and floral envelopes of *Atractylis gummifera* (Macaire, J. pr. Chem. i. 415); in the bark of the holly (*Ilex aquifolium*) (Bouillon-Lagrange); in the milky juice of *Ficus religiosa* (Nees v. Esenbeck), and in the glutinous substance which coats the branches of *Robinia viscosa*. (Vauquelin.)

Crude viscin is obtained by bruising the finely-scraped bark of the mistletoe, and kneading it with water as long as anything is thereby dissolved. A yellow, very viscid, and glutinous mass then remains, containing (besides woody fibre, part of which may be mechanically removed), pure viscin, a waxy substance soluble in alcohol, and a mass insoluble in alcohol and ether, called viscautschin. To obtain pure viscin, the crude mass is boiled several times with strong alcohol; the undissolved portion macerated five or six times with ether, at ordinary temperatures, for twelve hours; and the residue left on evaporating the ethereal extracts is kneaded first with alcohol, as long as this solvent takes up anything, and then with water. (Reinsch, Jahresb. 1860, p. 541.)

Viscin thus obtained is clear, colourless, nearly inodorous, and tasteless; has the consistence of honey at ordinary temperatures; may be drawn out into very fine threads; has the same density as water; becomes more fluid at 30°, and at 100° is as fluid as oil of almonds, and makes a greasy stain on paper. It has an acid reaction. (Reinsch.)

Viscin is decomposed by dry distillation (the boiling-point rising from 210° to above 275°), a mobile oil called viscene first passing over, then a greenish oil, and afterwards a crystalline buttery mass, while a black substance resembling asphalt remains in the retort.

Viscene is a very mobile yellowish oil, of specific gravity 0·85, and distilling almost completely at 226°. When mixed with soda-ley, it solidifies to a crystalline pulp, which, when distilled with water, gives off a fragrant oil called viscinol, while the remaining impure sodium-salt contains an acid called viscic acid, which, in the free state, is an oil having a strong acid reaction, and a faint odour like that of angelic acid. (Reinsch.)

Viscautschin is contained in the portion of crude viscin which is insoluble in alcohol and ether. To purify it, the residue is repeatedly treated with rectified oil of turpentine, which leaves woody fibre undissolved; the solution is mixed with water, and evaporated; the clear yellowish residue is treated with ether, in which it now dissolves; the ether is evaporated; and the residue is repeatedly washed with alcohol, and dried at 100°.

Viscautschin has a density of 0·978. It is extremely viscid and glutinous, being, in fact, the substance to which bird-lime owes its adhesive properties. At 120° it has the consistence of olive-oil. Crude viscin contains about 0·5 pt. viscin, 0·2 viscautschin, and 0·3 waxy matter. (Reinsch.)

VISCINOL. See the last article.

VISCOSIMETER. This name is given by Dollfus to an apparatus for measuring the viscosity of colouring liquids thickened with gum, &c., by comparing the time required by a given quantity of the liquid to pass through a certain aperture, with that required by an equal quantity of water.

VISCUM. The leaves and younger branches of the mistletoe (*Viscum album*) contain (according to Winckler), besides viscin, about 16·7 per cent. uncrystallisable sugar, 5·8 fat-oil, together with tannin, gum, &c., and a small quantity of a volatile odoriferous principle.

The ash of the leaves and branches contains, according to Fresenius and Will, and according to Reuling, the constituents given under *a* in the following table. C. Erdmann found in the leaves, 62·5 per cent. water and 3·85 ash, containing the constituents given under *b*; in the stalks of a mistletoe growing on an apple-tree he found 56·68 per cent. water and 1·9 ash, composed as under *c*. Reinsch found the ash of the stalks and leaves of a mistletoe growing on a Scotch fir, to contain, in 100 pts., the constituents given under *d*. The bark of the stem contains white viscin, gum, sugar, albumin, tannic acid, pectin, and similar substances (Reinsch); the ripe fruit contains resinous substances (bird-lime), gum, wax, &c.:—

Ash of Mistletoe.

	K^2O.	Na^2O.	CaO.	MgO.	$Fe'''Pb^4$.	P^2O^5.	SO^3.	CO^2.	SO^3.	Cl.	NaCl.

d.	22·0	3·8	21·7	11·7	6·5	14·1	1·7	15·8	1·7	0·6	

VITELLIN. This name was given to the albuminoïdal substance of the yolk of birds' eggs, now known to be merely a mixture of albumin and casein.

VITEX. The seed of *Vitex Agnus castus* is said to contain a peculiar bitter principle called **castine** (i. 814), a volatile acrid substance, a large quantity of free acid, and fat-oil. In Greece, the fresh and rather unripe berries are said to be added to the must of the grape, to render the wine more intoxicating, and prevent it from turning sour. (Landerer, Buchn. Repert. liv. 20; lxxxi. 229; Buchn. N. Repert. iii. 392.)

VITIS. See VINE and VIRGINIA CREEPER (pp. 999 and 1002).

VITRINOPAL. *Vitrite.*—The matrix of Bohemian pyrope, related to pitchstone, and containing, according to Wertheim, 83·72 per cent. silica, 3·58 ferric oxide, 7·57 lime, 0·67 magnesia, and 11·46 water. (Handw. d. Chem. ix. 288.)

VITRIOL. An old name for sulphates, still frequently used in commercial language, the several vitriols being distinguished by their colours, or by the metals which they contain: *e.g.*, white or zinc-vitriol, blue or copper-vitriol, red or cobalt-vitriol, green or iron-vitriol, lead-vitriol, nickel-vitriol, &c. Ferroso-cupric sulphates, obtained in the preparation of cupric sulphate on the large scale from ferruginous materials, are known as Admont, Bayreuth, and Salzburg vitriols (p. 593).

VITRIOL, OIL OF. Concentrated sulphuric acid.

VITRIOL-OCHRE (the *Pitticite* of Beudant) is a basic ferric sulphate found in the copper-mines of Fahlun in Sweden. It contains 15·9 per cent. SO^3, 62·4 Fe^2O^3, and 21·7 water = $2Fe^2O^3.SO^3.6H^2O$.

VITRITE. Syn. with VITRINOPAL.

VITRUM ANTIMONII. An oxysulphide of antimony, formed by fusing tetroxide of antimony with sulphur (i. 328).

VIVIANITE. Native ferrous phosphate. (See PHOSPHATES, iv. 564.)

VÖLCKNERITE. See HYDROTALCITE (iii. 219).

VOGLITE. A carbonate of uranium, copper, and calcium, occurring at Joachimsthal in Bohemia. (See CARBONATES, i. 798.)

VOIGTITE. A micaceous or chloritic mineral, occurring in the graphic granite of Ehrenberg, near Ilmenau, in the Thuringian Forest, forming green soft laminæ, mostly turned brown by weathering. Specific gravity = 2·91. It gives off water when heated, and before the blowpipe, exfoliates strongly, turns dark-brown, melts easily to a black glass, and gives with fluxes the reactions of iron. It is easily decomposed by hydrochloric acid, forming a yellow solution, with separation of tumefied silica. According to Schmid (Pogg. Ann. xcvii. 108), it contains 33·02 per cent. silica, 13·08 alumina, 33·15 ferric oxide, 7·28 magnesia, 1·99 lime, ·96 soda, and 9·52 water.

VOLBORTHITE. Calcio-cupric vanadate. (See VANADIUM, p. 991.)

VOLCANIC GLASS. Syn. with OBSIDIAN (iv. 169).

VOLCANITE. Selenide of sulphur, from Vulcano, one of the Lipari Islands.

VOLGERITE. Antimonic hydrate, $5H^2O.Sb^2O^5$, or $Sb''H^3O^5$, occurring as a white powder or crust with cervantite (i. 524), and resulting from its alteration.

VOLTAGOMETER. A peculiar rheostat or current-regulator, invented by Jacobi. (Pogg. Ann. lxxviii. 173).

VOLTAIC ELECTRICITY. See ELECTRICITY (ii. 414).

VOLTAITE. A ferroso-ferric sulphate, containing alumina, occurring at the Solfatara, near Naples, in opaque octahedrons and other monometric forms, having a resinous lustre, dull green brown or black colour, and greyish-green streak. According to Abich (Berg. u. hütt. Zeitung, 1842, No. 17), it contains 48·32 per cent. SO^3, 2·20 Al^2O^3, 17·65 Fe^2O^3, 11·6 FeO, 4·04 K^2O, 6·25 Na^2O, and 15·94 water, whence Rammelsberg deduces the formula $3(\frac{4}{5}Fe''.\frac{1}{5}K^2)SO^4.2(\frac{5}{6}Fe.\frac{1}{6}Al)'''(SO^4)^3.12H^2O$.—A similar mineral, containing manganous as well as ferrous oxide, has been found by Ulrich at the Rammelsberg mine, near Goslar in the Harz.

VOLTAMETER. An apparatus for measuring the force of an electric current by the quantities of hydrogen and oxygen evolved in the electrolysis of water. (See ELECTRICITY, ii. 433.)

VOLTZIN or **VOLTZITE.** An oxysulphide of zinc, Zn^5S^4O, occurring in implanted spherical globules at Rosières in Puy-de-Dome, and at the Elias mine near Joachimsthal in Bohemia. Hardness = 4·5. Specific gravity = 3·66. (Fournet, Ann. Ch. Phys. [2], xli. 426.—Landecker, Jahrb. geol. Reichsanstalt, iv. 120.)

VOLUME. The volume of a regularly-formed body may be calculated from measurements of its linear and angular dimensions. The volume of an irregular body may be found from its weight and specific gravity—that is to say, the weight of a unit-volume. If w be the weight of the body in grammes, and s its specific gravity, the fraction $\frac{w}{s}$ gives its volume in cubic centimetres.

The capacities of vessels are determined by filling them with water or mercury from a measuring tube or other vessel, whose capacity is previously known, or, when very great accuracy is required, by determining the weight of water or mercury at the standard temperature which fills the vessel. The capacities of wooden vessels may be estimated with sufficient accuracy, for commercial purposes, by filling them with measured quantities of sand or fine-grained seeds, taking care to shake the vessel from time to time, so that the grains may lie close together.

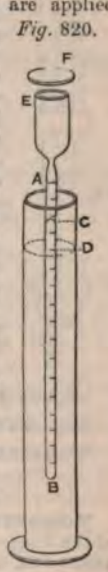
The volume of a large cavity, or vessel full of water, might in some cases be conveniently determined by dissolving a known weight of a soluble substance in the water, say 1 kilogramme of common salt, agitating the water to secure uniformity, and then analysing one litre of it. If this litre were found in the above case to contain one gramme of salt, it would be apparent that the cavity or vessel contained 1,000 litres of water.

VOLUME, ATOMIC or **SPECIFIC.** (See ATOMIC VOLUME, i. 440.)

VOLUMENOMETER, or **STEREOMETER.** These names are applied to instruments for measuring the volume of a solid body by the quantity of a liquid or of air which it displaces, and thence also determining its specific gravity. A very simple apparatus of this kind was used by Playfair and Joule in their experiments on atomic volumes (Chem. Soc. Mem. ii. 477). It consists of a globular flask provided with a narrow neck, about twelve inches long, and graduated from below upwards to indicate grains of water. The flask has a tubulure, accurately fitted with a ground stopper, for admitting the solid body to be measured. The instrument being filled to the mark 0° on the neck with water, oil of turpentine, or other liquid which does not act upon the solid, it is inclined on one side, the stopper removed, and the solid body carefully introduced. The stopper is then replaced, and the number of divisions through which the liquid is raised in the stem gives at once the volume of the body in grain-measures. Any other unit of graduation might of course be adopted.

The stereometer, invented by Captain M. K. Say, of the French Engineers, for determining the specific gravity of gunpowder, is an instrument which measures the volume of a body by the amount of air which it displaces.

Fig. 820.



The simplest form of this instrument is shown in *fig.* 820, where AB is a uniform graduated glass tube, open at the bottom, and communicating by a small hole with the glass vessel AE, which can be closed air-tight, by a piece of ground plate-glass, F. The instrument is immersed in a cylindrical glass vessel, full of clean mercury. If, now, AB be plunged into the mercury up to A, the zero of the scale, and the upper end of the vessel AC be then closed air-tight, we may, by again raising the tube, diminish the pressure on the air within by the weight of a measurable column of mercury; we also learn the increase of the volume of the air, provided we know the capacity of the divisions of the tube AB, which we shall suppose known. Thus suppose that, on the tube being raised, the mercury within stands at C, and without at D, then h being the ordinary barometric pressure of the atmosphere at the time, $h - \mathrm{CD}$ (inches) is now the pressure on the air within. If u be the capacity of the vessel AE, down to the zero A, we find that—

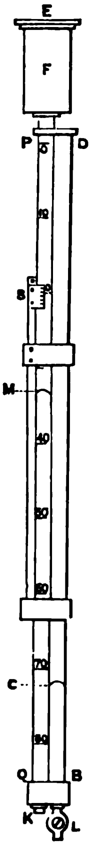
Under the pressure h, the air within has the volume u;
" " $h - \mathrm{CD}$ " " $u + \mathrm{vol.\ AC}$.

Hence, by the law that the volumes of gases are inversely as their pressures, we find—

$$\frac{u}{u + \mathrm{vol.\ AC}} = \frac{h - \mathrm{CD}}{h}, \text{ or } u = \frac{h - \mathrm{CD}}{\mathrm{CD}} \mathrm{vol.\ AC}.$$

Now, if we place any object, as sand, gunpowder, a soluble salt, &c., having the total volume v, in the vessel AC, we may proceed, as before, to find the volume $u - v$ of air still remaining in AE; and as u is already known, we thus find v, in cubic inches. From the volume v, the weight of the objects in AE, and the weight of a cubic inch of pure water at 60°, we may, by a simple calculation, find the specific gravity of the objects.

Fig. 821.



The stereometer has been rendered much more accurate and convenient by Prof. W. H. Miller, whose form of the instrument, as employed by him in finding the specific gravity of standard weights not allowed to be weighed in water, we will now describe, referring to the Phil. Mag. [1834] v. 203, and Phil. Trans. [1856] cxlvi. 799.

It consists of two glass tubes, PQ, DB (*fig.* 821), of equal diameter, communicating with each other at their lower ends, which are cemented into the oblong piece of iron, QB. Below the ends of the tubes are holes concentric with the tubes, that below PQ being closed by the screw K, while below DB is the stopcock L. On the upper end of PQ is the metallic cup F, which may be closed air-tight by the plate of glass E, smeared with lard. The tube PQ is accurately marked with a scale of centimetres, and the fractional parts of the divisions may be read off by the ivory scale S, a centimetre long, divided to every fifth of a millimetre. Some contrivances of Prof. Miller for avoiding error of parallax in this reading need not here be described.

To use this instrument, the object experimented on is placed in a cup within the vessel F; and mercury is poured into the tube at D, until both tubes are nearly full, and the surface in PQ stands exactly at zero of the scale. The plate E is now placed air-tight upon F, which being accomplished, the stopcock E is opened, and mercury is allowed to run out, until the difference of altitude of the mercury in the two tubes is nearly equal to half the height of the barometer at the time. Suppose the mercury in PR now to stand at the point M, and in DB at the point C; then the pressure within F is less than the atmospheric pressure by the weight of the column of mercury, MC, which corresponds to the column of mercury, CD, in the simple form of instrument above described (*fig.* 820). Hence, by the formula already given, we may find the volume of air within F, occupied or unoccupied by other objects. This is on the condition, however, that we know the volume PM, and it is necessary to determine accurately the capacity of the divisions of the tube PQ by the usual method of filling it with mercury, and weighing the portions as they run out, corresponding to given lengths of the tube. To facilitate this operation, F may be unscrewed, and the stopcock L substituted; and the instrument being inverted, mercury may be poured in through a tube-funnel at the opening K.

The results of this instrument are much affected by changes of temperature, and will be uncertain and inexact, except in the hands of a skilful and careful operator. Actual readings of a good barometer at the time are also necessary. (See Barometer, i. 509.) W. S. J.

VOLZIN and **VOLZITE.** Syn. with Voltzin and Voltzite.

VORAULITE. Syn. with Lazulite (iii. 477).

VORHAUSERITE. A massive dark-brown variety of serpentine from Monzoni in the Flemser valley, Tyrol: specific gravity = 2·45. (Oellacher, Jahrb. geol. Reichsanstalt, 1857, p. 258.)

VOSGITE. This name was given by Delesse to a green felspar from the porphyry of the Vosges, and from the gabbro of Mont Genèvre. Rammelsberg has, however, shown that it is merely a decomposed labradorite.

VULCANISATION. The process of combining caoutchouc with sulphur, at high temperature, whereby it acquires increased elasticity (i. 739). Oils heated with sulphur likewise form more or less tenacious and elastic masses; and Perra has shown (Compt. rend. xlvii. 878), that linseed-oil heated with chloride of sulphur yields a product of this nature, which he calls vulcanised oil. 100 pts. linseed-oil heated with 25 pts. chloride of sulphur (saturated with sulphur), yield a product of considerable hardness, though not so hard as ebonite. It is opaque, brittle when cold, permanent in the air; withstands the action of dilute mineral acids and alkalis, but is decomposed by them in the concentrated state; turns brown at 120°, and decomposes at a somewhat higher temperature; becomes strongly electric by friction.

VULCANITE, or **EBONITE.** Hardened caoutchouc.

VULPIC ACID. $C^{19}H^{14}O^5$.—An acid occurring in *Cetraria vulpina* (*Lichen vulpinus*, L.), a lichen which grows in Norway, and is there collected for mixing with nux vomica, as poison for wolves. It was first separated by Bebert (Ann. Ch. Pharm. ii. 342),—who called it vulpulin,—but in an impure state, so that it was regarded by Berzelius as identical with the colouring-matter of *Parmelia parietina*, and was afterwards mistaken for chrysophanic acid, till its true composition was demonstrated by Strecker and Möller (*ibid.* cxiii. 56), who designated it vulpic acid. It is very much like usnic acid (p. 570), from which it differs only by the elements of 2 at. water.

To prepare vulpic acid, the lichen is macerated with 20 pts. of lukewarm water, and a little milk of lime for six hours, and then strained; the residue is again exhausted with 10 pts. of warm water; the united extracts are slightly supersaturated with hydrochloric acid; and the yellow flocculent precipitate, consisting of vulpic acid contaminated with resin and chlorophyll, is purified by recrystallisation from strong boiling spirit or from ether. 100 pts. of the lichen yield about 12 pts. of the acid.

Vulpic acid separates from its ethereal solution on cooling, in transparent yellow needles; by slow evaporation it is obtained in well-defined, bulky, transparent, monoclinic crystals, having nearly the colour of rhombic sulphur. It is nearly insoluble in *water* even at the boiling heat, dissolves with difficulty also in boiling absolute *alcohol*, and separates for the most part on cooling; more easily in *ether*, but most abundantly in *chloroform*, which might therefore be advantageously used for extracting it from the lichen. It melts at a temperature above 100°, and solidifies in the crystalline form on cooling. At a stronger heat it decomposes, leaving a small quantity of charcoal, and giving off a yellow smoke, which condenses partly in brown drops, partly as a yellow powder.

Vulpic acid boiled with excess of *potash-ley*, of specific gravity 1·05 to 1·15, is resolved into oxatolylic acid (iv. 287), carbonic anhydride, and methylic alcohol:

$$\underset{\text{Vulpic acid.}}{C^{19}H^{14}O^5} + 3H^2O = \underset{\substack{\text{Oxatolylic}\\ \text{acid.}}}{C^{16}H^{16}O^3} + 2CO^2 + \underset{\substack{\text{Methylic}\\ \text{alcohol.}}}{CH^4O.}$$

But when boiled with baryta-water, it undergoes a different decomposition, yielding alphatoluic acid (p. 863), oxalic acid, and methylic alcohol:

$$\underset{\substack{\text{Vulpic}\\ \text{acid.}}}{C^{19}H^{14}O^5} + 4H^2O = \underset{\substack{\text{Alphatoluic}\\ \text{acid.}}}{2C^8H^8O^2} + \underset{\substack{\text{Oxalic}\\ \text{acid.}}}{C^2H^2O^4} + \underset{\substack{\text{Methylic}\\ \text{alcohol.}}}{CH^4O.}$$

Vulpates.—Vulpic acid is monobasic. The vulpates of the alkali-metals and alkaline earth-metals are soluble in water, and are easily obtained by treating the acid with water and alkaline hydrates or carbonates. The other vulpates are insoluble, and are obtained by precipitation.

Vulpate of ammonium, $C^{19}H^{13}(NH^4)O^5.H^2O$, forms yellow crystals, which dissolve in water and in alcohol, give off ammonia and water when heated, and are then no longer perfectly soluble in water.—The *barium-salt*, $C^{38}H^{26}Ba''O^{10}.2H^2O$, is obtained by boiling vulpic acid with water and barium-carbonate, and separates from the filtrate on cooling, in light-yellow needle-shaped crystals; but by recrystallisation from alcohol, it is obtained in orange-yellow needles containing a different amount of water.—The *potassium-salt*, $C^{19}H^{13}KO^5.H^2O$, crystallises in light-yellow needles, somewhat sparingly soluble both in water and in alcohol.—The *silver-salt*, $C^{19}H^{13}AgO$, is a yellow easily decomposible precipitate, which dissolves in ammonia, and likewise in boiling water, though in the latter case with partial decomposition. It blackens at 100°, but without much loss of weight.

VULPINITE. Anhydrite from Vulpino, near Bergamo.

VULPULIC ACID. } Syn. with VULPIC ACID.
VULPULIN. }

W

WACKE. Syn. with GRAUWACKE (ii. 842).

WAD. A term applied to ores of manganese of variable composition, consisting mostly of mixtures of the sesquioxide and dioxide of manganese. (See MANGANESE, iii. 813.)

WAGITE. A mineral from Nischni-Jagurt in the Ural, containing 26·0 per cent. silica, 66·9 zinc-oxide, 4·7 water, and 1·55 lime, together with traces of copper and iron, closely allied therefore to hemimorphite, but containing somewhat less water. It forms crystalline coatings of blue to green colour; hardness = 5·0, and specific gravity = 2·707. (Radoszkowski, Compt. rend. liii. 107.)

WAGNERITE. Phosphatofluoride of magnesium, found in the valley of Höllengraben in Salzburg. (See PHOSPHATES, iv. 569.)

WAIFA. The Chinese name of a yellow dyestuff, consisting of the undeveloped flower-buds of *Sophora japonica.*

WALCHOWITE. Retinite from the coal-mines of Walchow in Moravia (p. 98).

WALDHEIMITE. A green mineral resembling actinolite, from the serpentine of Waldheim in Saxony, containing, according to Knop (Ann. Ch. Pharm. cx. 360), 55·58 per cent. silica, 10·65 magnesia, 10·84 lime, 12·64 soda, 5·66 ferrous oxide, 0·36 manganous oxide, and 1·72 alumina. Hardness = 5·0. Specific gravity = 2·957.

WALL LICHEN. *Parmelia parietina.* (See LICHENS, iii. 587.)

WALNUT. *Juglans regia.*—The green shells of the fruit of this tree contain, according to Braconnot, a peculiar bitter principle, together with citric acid, malic acid, tannin, &c. According to Buchner, the alterable constituent of the shells and leaves of walnuts is not tannin, but a peculiar acid, juglandic acid, which, in contact with the air, is converted into a neutral brown insoluble substance called juglandin (iii. 444).

The ripe kernels contain 40 to 50 per cent. of a fat-oil, having a yellow or greenish-yellow colour, a mild taste and odour, and a specific gravity of 0·96. It solidifies at −27°, dissolves sparingly in alcohol, and dries easily in contact with the air. According to Saussure and Hermann, it contains from 79 to 80 per cent. carbon, and 10·5 to 11·0 hydrogen.

According to Vogel and Reischauer (Buchn. Repert. v. 106; vi. 1), fresh walnut-shells contain a peculiar principle, which they call mucin (iv. 143).

The ash of the wood, bark, and leaves of the walnut-tree in spring and autumn has been analysed by Staffel (Ann. Ch. Pharm. lxxvi. 379); that of the nuts themselves by Glasson (*ibid.* lxi. 343):

Ash of the Walnut-tree.

	Wood.		Bark.		Leaves.		Nuts.
	Spring.	Autumn.	Spring.	Autumn.	Spring.	Autumn.	
Ash per cent. of fresh substance . .	0·90	1·47	1·38	3·68	1.09	2·57	0·67
Ash per cent. of dry substance . .	10·03	2·98	8·75	6·40	7·72	7·0

Chloride of potassium	3·1	0·6	1·9	0·9	1·0	1·7	0·8

Several preparations from the leaves and young shells of the walnut are used in medicine; the oil of the nuts is used chiefly as a condiment. (Handw. d. Chem. ix. 555.)

WARWICKITE. A mineral occurring at Warwick in New York, in dark-brown or iron-black, indistinct, monoclinic crystals, of specific gravity 3·0 to 3·3. According to Shepard (Sill. Am. J. xxxiv. 313; xxxvi. 85), it contains 27·33 per cent. fluorine, 61·71 titanium, 7·14 iron, 0·80 yttrium, and traces of aluminium. According to L. Smith (*ibid.* xvi. 293) it contains 20 per cent. boric acid.

WASHINGTONITE. Titaniferous iron, from Litchfield, Connecticut (p. 847).

WASITE. This name was given by Bahr (Pogg. An. cxix. 572; Jahresb. 1863, p. 199) to a mineral resembling orthite, from Rensholm, an island near Stockholm, which he supposed to contain the oxide of a new metal, wasium; subsequent experiments, however, have led him to regard this supposed new oxide as most probably identical with thorina (Ann. Ch. Pharm. cxxxii. 227; Jahresb. 1866, p. 207). The so-called wasite contains alumina, ferric oxide, yttria, thorina, the oxides of cerium, lanthanum, didymium, and manganese, lime, and alkali.

WASIUM. See the last article.

WATER. Synonyms, *Wasser. Eau. Aqua. ὕδωρ.* Symbol, H^2O. Molecular weight, 18.—This substance, which plays so important a part in most terrestrial phenomena, was long regarded as an element or simple substance. Towards the end of the last century, however, the observations of Cavendish on inflammable air furnished the material by which Lavoisier was enabled to show that water is a compound of two distinct elementary substances, and thus to supply an important feature of the chemical system he had introduced. (See GAS, i. 780 *et seq.*)

Water occurs universally on the earth in one or other of the physical states which it is capable of assuming. As a liquid it constitutes the great mass of the oceans, seas, rivers, lakes, &c., which cover upwards of three-fourths of the earth's surface. Water also issues from the interior of the earth at many places as springs (pp. 1014, 1015). In the solid state, as ice and snow, it occurs permanently in the polar regions, and in lofty mountain districts, and periodically in the temperate zones. In the state of vapour it occurs invariably as a constituent of the aërial envelope of the earth, and to an extent determined by the temperature and other local conditions. (ATMOSPHERE, i. 437, and CLOUDS, i. 1027 *et seq.*) Water-vapour also occurs abundantly in the exhalations of volcanoes, during eruptions, and is continuously evolved from the interior of the earth at many places, as in Iceland and at the solfatara and fumaroles in the neighbourhood of volcanoes.

Water also occurs mechanically disseminated throughout the mass of the strata underlying the earth's surface, sometimes in considerable proportion, and even the most compact rocks contain a sensible amount of water. In many solid minerals and organic substances it also exists in a state of combination, sometimes to the extent of 40 or 50 per cent. and upwards. Thus allophane contains about 40 per cent. of water, chabasite contains 20 per cent., and brown iron ore 15 per cent. of water. Living plants and animals contain from 80 to 90 per cent. of water.

Properties.—Pure water is perfectly free from taste and smell, and within a range of temperature between 0° and 100° C., under the ordinary atmospheric pressure, it is a transparent, almost colourless liquid. The slight blue colour of water may be observed, as pointed out by Bunsen (Ann. Ch. Pharm. lxxii. 44), by looking at a shining white object through a column of pure water 2 metres long, contained in a tube blackened inside.

The density of water in the liquid state is about 770 times as much as that of atmospheric air, and is greatest at a temperature of about 4° C. (= 39·2° F.) (HEAT, iii. 58 *et seq.*) Taking the density at this temperature as unity, it is 0·999877 at 0° C., and 0·999107 at 15·5° C. The density of water is always taken as the standard of comparison in reference to which the densities of other solid and liquid substances are expressed (see SPECIFIC GRAVITY, p. 357 *et seq.*). In the United Kingdom the density of water at the temperature of 60° F. (= 15·5° C.) is taken as unity; but on the continent the density of water at the temperature of 4° C. is more generally adopted as unity. A cubic centimetre of pure water at this temperature, and under a pressure equal to a barometric column of 760 millimetres of mercury—29·922 inches—weighs 15·432349 grains or 1 gramme, which is the unit of weight in the metric system.

The following table (p. 1010) gives the weights of certain volumes of water in terms both of the metric system and of the system of weights and measures used in the United Kingdom.

Water is slightly elastic. By an increased pressure of one atmosphere its volume is reduced to the extent of ·000045 (Oersted), or ·000047 (Regnault), and under a pressure of 200 atmospheres its volume is said to be reduced $\frac{1}{12}$ (Perkins, Gilb. Ann. lxxii. 173; Pogg. Ann. ix. 554). The compressibility increases as the temperature

Grains.	Cubic centimetres at 4° C. grammes.	Cubic Inches at 62° F.	Pound.	Gallon at 62° F.	Cubic feet at 62° F.
1					
15·432349	1	·061027		·0002201	·0000353
252·456	16·3861759	1			
7000·	454·3457969	27·727	1	·1	·016046
70000·	4543·457969	277·276	10·	1	·16046
436,495	28315·	1728·	62·355	6·2355	1

rises. Thus at 0° C. it amounts to ·0000503; at 10·8° to ·000048; at 35° to ·0000456, and at 53° to ·000041. (Grassi, Ann. Ch. Phys. [3], xxxi. 437. See Elasticity, ii. 370.)

Taking the volume of water at 0° C. as unity, it expands to 1·042986 when heated to 100° C. (Kopp), and to 1·1016 when heated to 156·8°. (Mendelejeff.—See Heat, iii. 58.)

Water has a high capacity for heat, and its specific heat is taken as the standard of unity in reference to which the capacities of other substances for heat are expressed. (Heat, iii. 34.)

Water is a very bad conductor of heat; but when heat is applied to water from below the portion which is heated expands, and thus becoming specifically lighter, rises to the surface, while the colder and denser portion sinks, and is in its turn heated, until the whole mass acquires a uniform temperature. (Conduction of Heat, p. 73.)

At the temperature of 0° C. water becomes solid or freezes, and at the same time expands considerably. In that state it presents as ice crystalline structure, and as snow crystalline forms belonging to the hexagonal system, which are derivatives of the rhombohedron and six-sided prism.

Ice is colourless or slightly bluish, and transparent when it has been formed from water perfectly at rest. Its density is less than that of water at 0° C., or about 0·920 (Dufour, Compt. rend. lvi. 1079.—Duvernoy, Pogg. Ann. cxvii. 454). Consequently ice always floats on the surface of water, and since water attains its maximum density at the temperature of 4° above the freezing-point, it follows that when the water of lakes, rivers, &c., is cooled below that point, the colder portion remains at the surface, and when it reaches the freezing point, is there converted into ice, while the water below remains at 4° C.

The expansion which takes place in the freezing of water, to the extent of nearly $\frac{1}{11}$ the volume of the water, frequently causes the bursting of pipes and other vessels, and it is a powerful agent in the disintegration of rocks. (See Heat, iii. 78 *et seq.*)

Water contained in closed vessels and in a state of perfect rest may be cooled to —10° or —13° C. without becoming solid, and then on the slightest agitation it suddenly solidifies. (Heat, iii. 75.)

The conversion of water at 0° C. into ice is accompanied by liberation of heat, and in the melting of ice heat is absorbed or rendered latent to the same extent, without raising the temperature of the water above 0°, so that by applying heat to a mixture of ice and water, the temperature is not raised above 0° until after all the ice has been melted. The quantity of heat absorbed or liberated in the melting of ice or freezing of water is sufficient to raise the temperature of an equal weight of water to the extent of 79·2° C., so that when 1 pound of ice is mixed with 1 pound of water at 79·2°, the ice is melted and the whole of the water has a temperature of 0° C. (Heat, iii. 77.)

The melting point of ice is reduced slightly below 0° C. by increase of pressure to the extent of 0·00747° C. for each additional atmosphere. (Mousson, Ann. Ch. Phys. [3], lvi. 252. See Heat, iii. 76.)

Water evaporates at all temperatures when in contact with atmospheric air or other gases, and the vapour thus formed has a density and tension determined by the temperature (see Heat, iii. 81, 93). This evaporation takes place only from the surface, and to an extent proportionate to the volume, temperature, and dryness of the air with which the water is in contact. In a confined space this evaporation ceases when the air becomes saturated with water-vapour. In the open air it proceeds more rapidly in proportion to the extent of surface exposed, and when the air, which has become saturated with vapour, is constantly replaced by fresh air. Consequently a rapid current of air favors evaporation.

Under the ordinary atmospheric pressure—760 mm. or 29·922 inches—water boils at the temperature of 100° C., and is converted into upwards of 1600 times its volume of vapour. When the pressure is reduced to near a vacuum, the boiling point is lowered to nearly 0° C.; and it rises when the pressure is increased, as shown in the following table of the results obtained by Arago and Dulong (Ann. Ch. Phys. [2], xliii. 74):-

Pressure in atmospheres.	Temperature.	Pressure in atmospheres.	Temperature.	Pressure in atmospheres.	Temperature.	Pressure in atmospheres.	Temperature.
1	100°	5	153·1	12	190·0	25	226·3
1·5	112·2	6	160·2	14	197·2	30	236·2
2	121·4	7	166·5	16	203·6	35	244·8
3	135·1	8	172·1	18	209·4	40	252·5
4	145·4	10	181·6	20	214·7	45	265·9

The boiling point of water under the ordinary pressure is slightly influenced by the nature of the vessel in which it is heated, and by the state of its surface. Thus in vessels of glass or porcelain, with very smooth surfaces, water boils 1 or 2 degrees higher than in metallic vessels with a rough surface. (See Heat, iii. 87.)

The conversion of water into vapour is always attended with absorption of heat. The quantity of heat absorbed or rendered latent by water at 100° C., in becoming vapour at the same temperature, would raise the temperature of water 5·37 times as much from 0° to 100° C., so that when one pound of water vapour at 100° C. is mixed with 5·37 pounds of water at 0° C., the vapour is condensed and the 6·37 pounds of water have a temperature of 100° C. (See Heat, iii. 96 *et seq.*)

Water-vapour is colourless and transparent, and becomes visible only when partially condensed, as in the case of steam escaping into the atmosphere. The specific gravity of water-vapour at 100° C. is 0·622, as compared with air at the same temperature, and as compared with air at 0° C. it is 0·455.

Water is a very efficient solvent, so much so that there are very few substances, solid, liquid, or gaseous, which are not to some extent capable of being dissolved by water. Many substances, however, can be dissolved by water only in such minute proportions that for most purposes they may be regarded as practically insoluble. Thus calcic carbonate is generally classed among insoluble substance; but since it dissolves in from 10,601? (Fresenius) to 30,000 parts of water, it must be considered as a soluble substance, so far as relates to the character and contents of natural waters, since the above proportion amounts to at least 2·5 grains per gallon, and especially since calcic carbonate in some form or other is so frequently a constituent of the strata with which water comes in contact.

The solubility of different substances in water is very unequal. Some are readily soluble, and require only small proportions of water, others are but sparingly soluble. Generally the solubility of any particular solid or liquid substance is increased in proportion as the temperature is raised. (See Heat, iii. 79; and Solution, v. p. 349.) But there are many exceptions to this rule: thus cold water dissolves calcic sulphate in larger proportion than water at 100° C., and water at 120° C. does not dissolve any. Water at 0° C. dissolves nearly twice as much lime as water at 100° C.

In the case of gases, the amount capable of being dissolved by water is very much dependent on the pressure. Under the ordinary pressure it is generally larger in proportion as the temperature is lower. Thus water at 0° C. dissolves 68·61 times its volume of sulphurous acid gas, while water at 24° C. dissolves only 31·8 times its volume. There are, however, exceptions to this rule; between the temperatures of 0° and 25° C., water dissolves a constant amount of hydrogen, or 0·0193 of its volume. (Gases, Absorption of, i. 791 *et seq.*)

When the solution of a solid substance in water is not accompanied by chemical combination, there is very often a reduction of temperature produced, sometimes to a considerable extent. (See Heat, iii. 79, 80, and 112.) The solution of gases, on the contrary, is generally attended with increase of temperature, partly in consequence of the change of state in the gas.

Aqueous solutions of solid substances have a higher density than water; and, for any given substance, the density is proportionately higher according to the amount of substance in solution. The water-solutions of certain liquids and gases are also denser than water; but in many instances the density of such solutions is less than that of water. For some purposes the degree of density of water-solutions of any particular substance affords a sufficiently accurate indication of the amount of such substance in the solution, as in the case of sugar, soda, sulphuric acid, hydrochloric acid, ammonia, alcohol, &c.

The freezing-point of water-solutions is lower than that of water: thus sea-water freezes less readily than fresh water. When dilute solutions freeze, pure ice is formed, and thus the solution is concentrated. In cold countries salt is often obtained in this way. A solution containing 10 per cent. of common salt freezes at − 6° C.; one with 10 per cent. ammonium-chloride freezes at − 6·5° C.; one with 43 per cent. crystallised calcic chloride freezes at − 10° C., and a saturated solution of calcic chloride freezes at − 21° C. (**Rudorf**, Poggend. Annal. cxiv. 63.)

The boiling-point of water is raised when it contains solid substances in solution, and to an extent proportionate to the amount of substance in solution. (See HEAT, iii. 89.) Liquid and gaseous substances dissolved in water sometimes cause a rise and sometimes a depression of the boiling-point.

Certain liquids when mixed with water form two solutions which do not mix, each liquid acting as a solvent to the other; thus water dissolves 10 per cent. by measure of ether, while ether dissolves about $\frac{1}{36}$ of its bulk of water, and when water is mixed with more ether than it can dissolve, these saturated solutions are formed in two separate layers.

The saturated solutions of solid substances which are capable of crystallising deposit these substances in a crystalline form when the water is evaporated, and the crystals thus produced are generally larger and more regular when the evaporation goes on slowly, and without disturbance of the liquid. (CRYSTALLISATION, ii. 114 *et seq.*)

Water, in its chemical characters, is a remarkably neutral substance, the relatively basylous and chlorous characters of its constituents being so nearly compensated that it is capable of assuming either relation according to the nature of the substance with which it reacts or combines. Its basyl constituent may be replaced, either by a basylous or chlorous substance (METALS and METALLOIDS, iii. 937), so as to produce a great variety of compounds whose constitution is referrible to the type of water.

Water, though itself an eminently neutral substance, often exercises an important influence in determining the chemical activity of other substances, not only as a solvent by rendering one or more of the substances concerned in a particular reaction, liquid, and in so far more susceptible of chemical action, but also by taking part in the reaction itself; thus, for instance, concentrated sulphuric acid and iron present no reaction even when heated to the boiling-point, and this is also the case with concentrated nitric acid, and the metals tin, lead, and iron. When water is added, however, vigorous chemical action is at once set up, and in numerous other instances the presence of water, in some condition, is essential to chemical action. The chemical processes taking place in the organisms of plants and animals require the presence of water, and in the alteration of minerals it is equally necessary, both as the solvent of products of decomposition, and as the medium for rendering efficient the carbonic acid, oxygen, &c., by which alteration is produced.

Composition.—The composition and constitution of water have already been treated of. (HYDROGEN, OXIDES OF, iii. 195.)

Decomposition.—Water may be decomposed in various ways; viz.

1. With liberation of both constituents.

By Heat.—Grove first observed that water is decomposed by heat. Deville considers that this decomposition (*dissociation*) takes place between 1000° and 2000° C., and that at a lower temperature the greater portion of the gases again combine together.

By Electricity.—When two platinum-plates are immersed in a vessel of water, slightly acidulated with sulphuric acid to increase its conducting power, and these plates are connected with the poles of a voltaic battery, hydrogen and oxygen gases are evolved at the surfaces of the plates. If these gases are collected in two glass tubes filled with water and inverted over the platinum-plates, the volume of the hydrogen gas evolved at the one plate will be found to be exactly double that of the oxygen gas evolved at the other plate, except in so far as the greater solubility of oxygen gas in water affects this relation. (ELECTROLYSIS, ii. 432 *et seq.*)

2. With liberation of one constituent only:—

The *metals of the alkalis and alkaline earths* decompose water at the ordinary temperature, disengaging hydrogen and forming oxides. Many other metals decompose water or water-vapour in the same way at temperatures varying from 100° C. to a white heat. Others do not decompose water under the influence of heat alone.—*Iron* and many other metals decompose water at the ordinary temperature, only in the presence of an acid.—*Zinc* and some other metals decompose water under the influence of heat, and in the presence of an alkali.

Carbon also decomposes water-vapour at a red heat, yielding hydrogen, some carbonic oxide, and a little carburetted hydrogen.

Some of the lower oxides decompose water, or water-vapour, with evolution of hydrogen, either at the ordinary temperature or with the aid of heat.—*Hydrated silicious oxide* decomposes water in presence of acids or ammonia, forming silicic acid.—

Carbonic oxide decomposes water-vapour at a red heat, yielding hydrogen and carbonic acid.

Chlorine decomposes water under the influence of light, and water-vapour at a red heat, with formation of hydrochloric acid and liberation of oxygen. Water-vapour heated to redness with *bromine-vapour* in excess, is decomposed in a similar manner. This decomposition is not effected by *iodine.*

3. Both constituents enter into other combinations:—

Phosphorus heated with water in presence of an alkali decomposes it, with formation of phosphoretted hydrogen and hypophosphorous acid. According to Schönbein, water is decomposed when boiled in contact with nitrogen-gas, nitrous acid and ammonia being formed:

$$2H^2O + 2N = (NH^4)NO^2.$$

Many chlorides and bromides decompose water, forming oxides and hydrochloric or hydrobromic acid. Thus *phosphorus chlorides* yield, with water, phosphorous or phosphoric acid and hydrochloric acid:

$$PCl^3 + 3H^2O = 3HCl + PH^3O^3;\ \text{and}\ PCl^5 + 4H^2O = PH^3O^4 + 5HCl.$$

Some metallic chlorides are decomposed by contact with water, forming oxychlorides and hydrochloric acid. (ANTIMONY, i. 318, 327, and BISMUTH, i. 591.)—*Aluminic* and *magnesic chlorides* decompose water when their solutions are boiled, yielding alumina or magnesia, while hydrochloric acid escapes.

Many metallic chlorides, bromides, and iodides decompose water-vapour with the aid of heat, yielding the corresponding oxides and hydrochloric acid. Certain metallic sulphides decompose water-vapour in a similar manner.

Arsenious acid and *sulphurous acid* decompose water in presence of chlorine, with formation of arsenic acid or sulphuric acid and hydrochloric acid.

Certain *oxides* decompose water, with formation of a product containing the elements of both substances. Thus *sulphuric anhydride* and water yield hydric sulphate; *calcic oxide* and water yield calcic hydrate:

$$SO^3 + H^2O = SH^2O^4,\ \text{and}\ CaO.H^2O = CaH^2O^2.$$

Production.—Water is formed whenever hydrogen-gas, or a combustible substance containing hydrogen, is burnt in oxygen or atmospheric air. (HYDROGEN, iii. 192; FUEL, ii. 722; and EREMACUSIS, ii. 497.) Water is also produced when hydrogen, or organic and other substances containing hydrogen, are exposed to a bright red heat in contact with easily reducible metallic oxides or other substances capable of yielding oxygen under those conditions. (OXYGEN, iv. 308.)

Combinations.—Water enters into combination with other substances in various ways. In some of the compounds which it forms, water exists as such, while others more probably contain only its elements in the same relative proportion as in water. (HYDRATES, iii. 179; ATOMIC WEIGHTS, i. 458 *et seq.*)

With many saline and other substances, water combines in definite equivalent proportions, producing compounds which are sometimes capable of assuming regular crystalline forms. In such cases it exists as *water of crystallisation*, and the crystalline form of such substances is essentially connected with the amount of water they contain. The amount of water which may be contained in crystallised substances varies from 1 to 24 atoms, and the same substance may combine with water in several different proportions. Thus borax, crystallised from solution at the ordinary temperature, is combined with 4½ at. of water, and when crystallised between 60° and 80° C., it is combined with 2 at.: in the one case it forms oblique rhombic prisms ($2NaHB^2O^4 + 9aq.$); in the other case, octahedrons ($NaHB^2O^4 24aq.$). Sodic carbonate crystallised from solution at the ordinary temperature forms rhomboidal prisms ($Na^2CO^3 + 10aq.$), at a higher temperature it crystallises as $Na^2CO^3 + 8aq.$, or as $Na^2CO^3 + 5aq.$, and from a boiling solution it crystallises as $Na^2CO^3 + 1aq.$ in rectangular tables.

The presence of water of crystallisation combined with a salt, often influences its colour; thus anhydrous cupric sulphate is white, while the crystalline salt $Cu''SO^4 + 5aq.$ is blue. Anhydrous nickel sulphate is yellow and the crystalline salts are green.

In some cases, water of crystallisation is so feebly combined that it is gradually separated when the substance containing it is exposed to dry air. (EFFLORESCENCE, ii. 362.) Water of crystallisation is always expelled by heat, and generally at a temperature of from 100° to 120° C. Some crystallised substances require a higher temperature; but in any case the crystals become opaque and friable in proportion as the water of crystallisation is expelled, and at last disintegrate and fall to powder. Certain substances retain a portion of their water of crystallisation more tenaciously than the rest. Thus cupric sulphate retains one molecule of water when dried at 100°, and does not give it up until heated to 200° C. (HYDRATES, iii. 180.) Potash-alum loses 10 at. water at 120°, and the remaining 2 atoms are not separated under 200° C. Water of crystallisation may also be abstracted from crystals by immersing them in a liquid which attracts water but does not dissolve the substance. Thus alcohol abstracts water from crystallised sodic sulphate, and oil of vitriol abstracts it from cupric sulphate.

Substances containing water of crystallisation frequently melt with ease when heated, and then become solid again after the heat is maintained some time, and the water of crystallisation has been evaporated.

Many amorphous substances also contain water in a state of combination similar to that in which it exists in crystals.

Substances which are very soluble in water often attract water from the atmosphere to such an extent as to form a solution, and are then called *deliquescent*, as for instance calcic chloride. (Deliquescence, ii. 309.) Many insoluble pulverulent substances also attract water from the air in the same manner, as for instance cupric oxide, silica, &c., and are termed *hygroscopic*. Organised substances, such as wood, hair, &c., have the same property (Hygrometry, iii. 233). Some liquids have the same property, as for instance sulphuric acid.

Natural Water.—The constant evaporation from the surface of all masses of water exposed to the atmosphere, the diffusion of the water-vapour throughout the atmosphere, and its subsequent condensation there to the liquid or solid state, give rise to an incessant circulation of water, which enables it to play an important part in a variety of natural phenomena. Of the total amount of condensed atmospheric vapour falling upon the surface of continents and islands, a certain portion, which varies in different localities according to the relative permeability and configuration of the superficial strata, is absorbed and penetrates downwards, until it reaches a less permeable stratum, above which it accumulates, and taking an underground course, determined by the inclination of the strata, towards some point where they crop out again at a lower level, reappears at the surface as springs along the line of outcrop. It is there discharged into, or forms the source of a stream, and thence flowing along the surface, such streams unite to form a river, which finally falls into the sea. If the permeable or "water-bearing" strata do not crop out again at the surface, but dip down under others which are impervious, the water they absorb may penetrate to very considerable depths, and will not then reappear at the surface as a spring, unless it meets with a fissure through which it may be forced upwards—either by the hydrostatic pressure of the water in the upper extremity of the water-bearing strata, or by some other force acting from below—or unless the overlying strata are bored through so as to form an artificial spring. (See Artesian Wells, *Ure's Dictionary of Arts, Manufactures, and Mines*, i. 192 *et seq.*)

As a consequence of the remarkable solvent power of water, it takes up whatever soluble substances it may meet with in each stage of its passage from the state of vapour in the atmosphere to its discharge into the sea. (Geology, Chemistry of, ii. 834 *et seq.*) For this reason natural water never occurs absolutely pure, and having regard to this circumstance, the different kinds of natural water may be classified under the heads of *rain-water*, *spring-water*, *river-water*, and *sea-water*.

Rain-water approaches nearer to absolute purity than any other kind of natural water. When collected in suitable vessels, it contains only such dissolved substances as it can derive from the atmosphere. These consist chiefly of atmospheric gases—oxygen, nitrogen, and carbonic anhydride, together with organic substance, and particles of dust and such other mechanical admixtures as are sometimes present in the air about towns, factories, &c. (Atmosphere, i. 439 *et seq.*)

The total amount of gases dissolved in rain water is about 25 cubic centimetres per litre. The ratio of the oxygen to nitrogen by volume is greater in this gas than in atmospheric air, on account of the greater solubility of oxygen in water. (Atmosphere, i. 437.—Gases, Absorption of, ii. 790.) Analysis has given the following percentage results by measure:

	Baumert.	Peligot.
Oxygen	33·7	31·2
Nitrogen	64·5	66·4
Carbonic anhydride . .	1·8	2·4

Rain-water probably always contains *ammonia* to some extent, either as carbonate or combined with other acids. The amount is greater just after the commencement of rain than when it has continued for a long time. Boussingault found ·004 grm. per litre in rain-water collected in Paris, and in that collected in the country only ·00079 grm. per litre. Dew he found to contain from ·001 to ·006 grm. per litre. In water condensed from fog he found ·0497 grm., and on another occasion in Paris ·1378 grm. per litre. Barral found from ·002 to ·003 grm. per litre in rain-water collected in Paris

(Ann. Ch. Phys. [3], xxxix. 257; xl. 129). In rain-water collected at Lyons, Bineau found as much as ·03 grm. per litre. The amount of ammonia in rain is also much larger in summer than in winter.

Nitric acid is commonly present in rain-water, chiefly in combination with ammonia. The amount varies considerably, and is greater in rain falling during thunder-storms. Boussingault estimated the average amount at ·0002 grm. per litre. In rain-water, collected during a hail-storm in Paris, he found ·055 grm. per litre, and in the melted hail ·083 grm. per litre; on other occasions from ·0004 to ·0021 grm. per litre in rain-water, from ·0003 to ·004 grm. per litre in snow-water collected in Paris, and in water condensed from fog ·0101 grm. per litre. In the country (Alsace) he found in rain-water from ·00004 to ·00028 grm. per litre; in that collected during a thunder-storm ·0021 grm. per litre; and in water condensed from fog, from ·0004 to ·0018 grm. per litre.—Barral found from ·002 to ·036 grm. per litre in rain-water collected in Paris. The amount is less after rain has continued for some time, and it is generally greater in summer than in winter. (Compt. rend. xxxiv. 283, 824; xxxv. 427; xlvi. 1123, 1175.)

Nitrous acid is also present in rain-water, and according to Schönbein, ammonia-nitrite is formed by the direct combination of nitrogen with water. Lawes, Gilbert, and Way estimate the average amount of nitrogen contained in rain-water, as ammonia, nitrous and nitric acid, at about ·985 grm. per litre. (See Report of the Brit. Assoc. for 1854.)

Rain-water perhaps always contains a small amount of *organic substance*, in consequence of which it readily becomes putrid when kept some time. Angus Smith found 0·01 grm., Marchand ·024 grm., and Chatin ·05 grm. per litre.

Sulphuric acid is often found in the rain-water falling in towns, and near factories where sulphurous gas is generated and discharged into the atmosphere. A. Smith found ·1 grm. per litre in rain-water collected at Manchester.

Rain-water sometimes contains a very small amount of *hydrochloric acid, sodic* or *calcic chlorides*, and other *saline substances*. Barral found the rain-water collected in Paris gave, on evaporation to dryness, a residue amounting to ·022 grm. per litre, and that collected in the neighbourhood of Paris ·0078 grm. per litre.—A. Smith also found a minute quantity of coal-ash in rain-water collected in Manchester.

Rain-water is stated by some observers to contain *iodine*. (Chatin, Compt. rend. xlvi. 399; l. 420; li. 496.—Marchand, *ibid.* xlvi. 806.—De Luca, *ibid.* xlvii. 644; xlix. 170; li. 177.)

Spring-water, whether derived from natural or artificial springs, or from wells, always contains a very much larger amount of dissolved substance than rain-water does, in consequence of its having been for some time in contact with strata from which it has extracted various constituents, partly by its own solvent action, and partly by the aid of the carbonic anhydride originally contained in it as rain-water or derived from subterranean sources. The amount and nature of such dissolved constituents vary of course according to the kind of strata traversed by the water, and the distance that it may have passed through them since the time when it fell as rain upon the surface of the earth.

The depth from which spring-water rises to the surface is in some cases not more than a few feet, in others it rises from very considerable depths. The water of the artesian well at St. Grenelle rises from a depth of 1,800 feet, and the water of many natural springs probably rises from still greater depths.

The temperature at which spring-water issues from the surface differs from a few degrees above 0° C. up to 100° C. With the exception of those springs which occur in mountain ranges near the limits of perpetual snow, and are supplied from glaciers, &c., and some of those which are situated near active volcanoes, there appears to be an intimate connection between the temperature of spring-water and the depth from which it rises. The probable existence of such a relation has received considerable support from the fact that the water from artesian wells has been observed to have a temperature higher in proportion to the depth from which it rises. Thus the water of St. Grenelle has a temperature of 28° C. In many cases the temperature of spring-water presents little or no variation throughout the year. Those kinds which have the highest temperature appear to be most constant in this respect, and to have maintained a uniform degree of heat for many years. Even cold spring-water has a temperature more or less above the mean local temperature of the places where it issues from the earth, and it is only those kinds of spring-water rising from depths within the influence of the local atmospheric changes of temperature, that present any considerable variation of temperature in the course of the year. The mean temperature of such spring-water is either the same as the mean local temperature or but very little above it.

As a rule the general character of the dissolved contents of spring-water does not present much variation except in so far as concerns the relative proportions of the

The gaseous contents of mineral water also vary considerably in amount. In some cases it is very small, in others so large that the gas is evolved from the water as it ascends, and the water issues together with a copious discharge of undissolved gas. The constituents of the gaseous contents of mineral water are chiefly *carbonic anhydride, nitrogen*, and *oxygen*, sometimes also *sulphuretted hydrogen* and *carburetted hydrogen*.

Since the difference between the various kinds of mineral water consists chiefly in the nature and relative amount of their dissolved contents and in the proportions which the constituents of those contents bear to each other, they may be conveniently classified according to the predominance of some one or other constituent, and on this principle they may be arranged under the following heads, viz:

I. *Carbonated water*, in which the saline contents consist chiefly of carbonates. According to the nature of the basic constituent present in largest proportion, such water may be either:

1. Alkaline, like the water of Vichy, Bilin, Ems, Fachingen, Töplitz, &c.
2. Magnesian, like that of Schwalbach, Göppingen, Spa, &c.
3. Calcareous, like that of Griessbach, Karlsbrunnen, etc.

Mineral water belonging to any one of these subdivisions may also contain ferrous carbonate, and is then termed *chalybeate*, as for instance, the water of Spa.

If the water contains a large amount of carbonic anhydride in solution it is termed *acidulous*, like the water at Vichy, St. Nectaire, Fachingen, &c., and when it contains sulphuretted hydrogen, it is called sulphuretted, like the water at Schinznach.

II. *Sulphatic* water, in which the saline contents consist chiefly of sulphates, and, according to the preponderating basic constituent, this may be either:

1. Alkaline, like the waters of Carlsbad, Bristol, Püllna, Sebastiansweiler.
2. Magnesian, like the water of Saidschütz.
3. Calcareous, like the water of Pyrmont, Epsom, Bath, Schwarzsee.

Sulphatic water sometimes contains ferrous sulphate, and is then termed *chalybeate*. Sometimes it contains a large amount of carbonic anhydride in solution, and is then termed *acidulous*, as in the water of Carlsbad, Pyrmont, and it is frequently *sulphuretted*, like the water of Schwarzsee, Sebastiansweiler.

III. *Chlorinated water*, in which the saline contents consist chiefly of chlorides, and is, according to the preponderating basic constituent, either:

1. Alkaline, like the water of Wiesbaden, Leamington, Harrowgate, Cheltenham, Selters, Homburg, Kissingen, Kreutznach, Alexisbad, Aix-la-Chapelle, Weilbach.
2. Magnesian, like the water of the Dead Sea, Elton lake, and some other lakes of eastern Europe and Asia.

Chlorinated water is sometimes *chalybeate*, and may contain both ferrous sulphate and chloride, or ferrous carbonate, like the water of Alexisbad, Homburg, Hermannsbad. It is sometimes also *acidulous*, like the water of Homburg, Kissingen, and Wiesbaden, and sometimes *sulphuretted*, like the water of Harrowgate, Aix-la-Chapelle, Weilbach.

IV. *Silicious water*, in which the saline contents consist chiefly of silicates, like the hot spring-water of Iceland.

The accompanying table contains the analyses of some of the most celebrated kinds of mineral water, which have been selected as types of the several classes above described.

River-water, though generally originating to a great extent from natural springs, almost always contains a smaller amount of dissolved contents than the generality of fresh spring-water. This is partly the result of dilution by the direct influx of rain or some other form of meteoric water, glacier streams, &c., and is sometimes also in part due to the disengagement of carbonic anhydride when the water of the springs feeding a river comes in contact with atmospheric air as a flowing stream, and there is a consequent separation of substances which, like calcic carbonate, &c., were chiefly held in solution by that gas in the spring-water.

The total amount of dissolved contents in river-water varies less than in spring-water. It rarely exceeds from ·3 to ·4 grm. per litre, and is sometimes very much less in the case of rivers flowing through districts where crystalline or schistose rocks prevail, when the water is sometimes almost as pure as rain-water. The gaseous contents are the same as in fresh spring-water, but the amount of carbonic anhydride is generally less than in most spring-water, and from the free exposure of the water to the atmosphere, the proportion of oxygen to nitrogen, under normal conditions, is the same as in rain-water, or as 1 to 2 by volume, being greater than in atmospheric air in consequence of the greater solubility of oxygen in water. (See ATMOSPHERE, i. 437, and GASES, ABSORPTION OF, ii. 790.)

The amount of dissolved *organic substance* in river-water is generally much greater than in spring-water. This is due to the surface drainage of river-basins being discharged into the rivers, which are the natural drains of the country they flow through. The organic substance thus constantly carried into rivers, and diffused throughout the running water containing dissolved oxygen, is exposed to its influence and gradually decomposed, being ultimately converted into the final products of such change, viz., carbonic anhydride, water, ammonia, nitrites, and nitrates (EREMACAUSIS, ii. 497). Thus the oxygen dissolved in river-water, and constantly renewed by the contact of the flowing water with the atmosphere, plays an important part in the natural purification of rivers, and in preventing the putrefaction or accumulation of organic substance in their water. In the case of rivers flowing through populous districts, and receiving the drainage of the towns situated within their basins, in addition to the natural surface drainage, the quantity of putrescible organic substance thus constantly carried into the rivers as sewage may be so large that this natural process of purification is inadequate to prevent putrefactive change, especially during hot weather, when the temperature of the water rises considerably (FERMENTATION and PUTREFACTION, ii. 623, *et seq.*). The condition of the Thames within London, during the autumn of 1859, when the sewage of the whole population was discharged directly into it, affords an illustration of the consequences of such contamination of a river. Some observations made by Professor Miller at that time on the gaseous contents of the water taken at different points of the Thames at low water, also serve well to elucidate both the natural process of purification taking place in river-water, and the influence of sewage contamination on the condition of the water, as will be seen from the following tabular statement:

Thames water taken at	Kingston.	Hammersmith.	Somerset House.	Greenwich.	Woolwich.	Erith.

Ratio of oxygen to nitrogen	1 : 2	1 : 3·7	1 : 10·5	1 : 60	1 : 52	1 : 8·1

From these results it will be seen that while the water at Kingston was in a normal state of aëration, the influence of sewage contamination in abstracting oxygen began to become evident at Hammersmith. At Somerset House it was still more marked, and at Greenwich and Woolwich the oxygen had been almost entirely consumed; but by the time the water reached Erith its state of aëration had greatly improved as regards oxygen. (See also R. A. Smith, Mem. Philos. Soc. Glasgow, vi. 154, *et seq.*)

In addition to the dissolved contents of river-water, saline, organic, and gaseous, it almost always contains *mechanically suspended substance*, the amount of which varies according to the quantity of rain passing into the rivers at different seasons, and also according to the nature and extent of the surfaces drained by them. The amount of suspended substance in the Thames is sometimes as much as ·5 grm. per litre at low water, and ·2 grm. per litre at high water. In the Seine at Paris, the amount of suspended substance varies from ·007 to 118 grm. per litre; in the Rhine at Bonn it is from ·017 to ·205 grm. per litre; and in the Meuse from ·014 to ·474 grm. per litre. In the water of the Mississippi the average amount of suspended substance is about ·8 grm. per litre; in that of the Ganges it is stated to vary from ·2 to 2· grm. per litre, and in that of the Yellow River to be still larger.

The water of lakes which are situated among crystalline or schistose rocks, and have an outlet, is sometimes almost as pure as rain-water. Lakes through which rivers flow, as the Rhone flows through the lake of Geneva, may be considered as mere local expansions of the rivers, and their water will have nearly the same dissolved contents as the river-water. On the contrary in lakes which have no outlet, like the Dead Sea, and many of the salt-water or soda lakes of Eastern Europe, Asia, Africa, and America, the water though sometimes fresh, is often so highly charged with saline substances, which have accumulated by the evaporation of the water flowing into the lakes, that in the dry season certain of the saline contents are deposited, as in the case of the salt lakes of Russia, Central Asia, Africa, and America (p. 184); the soda lakes of Egypt, Asia, Mexico, and Hungary; the borax lakes of Thibet, &c.

Sea-water is essentially a chlorinated alkaline mineral water, the saline contents of which consists chiefly of sodic, magnesic, potassic, and calcic chlorides and sulphates, together with a number of other substances in much smaller proportion and some in very minute amounts.

The total amount of dissolved contents in the water of the ocean at long distances from land varies from about 28 to 39 grms. per litre. It is largest near the equator and smallest near the poles. The greater evaporation of water in tropical regions than in temperate or polar regions, and the unequal influx of fresh water from rivers or as rain, tend to produce local differences, which are to a great extent compensated by currents. Forchhammer fixes the mean amount of dissolved contents in the water of the ocean at 34·404 grms. per litre (Phil. Trans. clv. 203 *et seq.*). In the water of seas which are partly shut in by land, the amount of dissolved contents is influenced by the amount of evaporation relatively to the quantity of fresh water carried into them by rivers. Thus in the water of the Baltic, the amount of dissolved contents varies from about 5 to 18 grms. per litre at different parts, while in the Mediterranean it varies from about 36 to 40 grms. per litre.

In the water of the ocean there appears, according to Forchhammer, to be generally but little variation in the relative proportions of the chief constituents of its contents, as will be seen from the following table, deduced from the mean results of his numerous analyses:

	SO^4.	Mg.	Ca.	Total saline contents.	Chlorine.
Maximum	14·51	6·768	2·257	181·40	100
Mean	14·26	6·642	2·114	181·10	100
Minimum	13·98	6·570	2·050	180·60	100

Some of the analyses of sea-water indicate much greater local variations in the relative proportions of certain substances, and it is very probable that a variety of circumstances, such as submarine springs or volcanic eruptions, &c., may tend to affect the composition of its dissolved contents either permanently or for a time at certain points.

In addition to the substances already mentioned, sea-water contains about ·3 grm. per litre of *bromine*, and very minute amounts of *iodine* and *fluorine*; also *silica, phosphoric acid* (Voelcker, Chem. Gaz. viii. 346), *calcic* and *magnesic carbonates* in small proportions. The amount of carbonates is largest near the land, and is very small in the water of the ocean (J. Davy, Ed. New Phil. Journ. xlvii. 320). *Silver, lead, copper,* and *arsenic* have been detected either in sea-water, the ashes of marine plants or animals, or in the deposit formed inside the boilers of ocean steamers (Malaguti, Durocher, Sarzeaud, Ann. Chim. Phys. [3], xxviii. 122.—Field, Chem. Gaz. 1857, p. 93.—Daubree, Compt. rend. xxxii. 827). In fact since the ocean is the common recipient of by far the greater part of the water discharged from springs and constituting rivers, most of the material abstracted by their water from the interior and surface of the earth passes into it, and all substances which exist in spring-water may be expected to exist, to some extent, in sea-water.

The gaseous contents of sea-water are nitrogen, oxygen, and carbonic anhydride, amounting altogether to from 10 to 30 c.c. per litre, according to different observers. The amount appears to be greater at a depth of about 2,000 feet than near the surface, but at about 4,000 feet the water contains scarcely any dissolved gases. The relative proportions of the gases have not been estimated with much accuracy. Carbonic anhydride is stated to vary from 2 to nearly 40 c.c. per litre; oxygen from about 1 to 3 c.c. per litre, and nitrogen from 12 to 17 c.c. per litre. (Aimé, Pogg. Ann. lx. 404.—Hayes, Sill. Am. J. 1851, 421; Compt. rend. vi. 616.—Lewy, Ann. Ch. Phys. ii. 535, viii. 425, xii. 5.—Bischof, Chem. Phys. Geol. i. 113.—Thorpe, Chem. Soc. J. [2] v. 189.)

From the facts already stated as to the dissolved contents of the various kinds of natural water, it will be possible to form some general idea of the geological importance attaching to the constant circulation of water from the ocean to the land by evaporation, and then back again to the ocean, after having penetrated through the rocks constituting the land, to various depths in the interior of the earth.

The mere mechanical action of the water discharged by rivers, in abrading the rocks with which it comes in contact after falling as rain, in sweeping away the particles detached by it and by other disintegrating influences, and in transporting the finely divided débris to the ocean, is alone a very potent agent of geological change. The quantity of solid material thus conveyed from the land to the sea, as mud, by such rivers as the Amazon, Yang-tse-Kiang, Mississippi, Nile, Ganges, and Danube, is enormous. It has been estimated that the suspended material annually discharged into the sea by the Mississippi is equal to 4,000 million cubic feet of clay, and that the quantity thus conveyed into the Bay of Bengal by the Ganges and Brahmapootra amount to ten times as much. (Lyell's *Principles of Geology.*)

But the suspended mud of rivers constitutes only a part of the material they convey into the ocean. A further and probably equal quantity is discharged into it in a state of solution. The compositicn of the dissolved material carried into the sea by rivers differs widely from that of the dissolved contents of sea-water, as will be seen from the following comparison of the relative proportions of the chief constituents in both cases:

	CO^2.	Ca.	K.	SO^4.	SiO^2.	Mg.	Na.	Cl.
Dissolved contents of sea water . .		2·114	·305	14·26	trace	6·64	57·	100
" " river-water	807·	568·	43·	228·	10·	36·	43·	100

From this comparison it will be seen that precisely those substances which are present in the dissolved contents of sea-water in the smallest amount, relatively to chlorine, exist in the dissolved contents of river-water in the largest amount relatively to chlorine, and are carried into the sea in the largest quantities. These substances, however, do not accumulate in sea-water; but are abstracted from it by marine plants and animals, whose growth is probably to a great extent supported by the dissolved material conveyed into the sea by rivers, and its chief constituents are found in the ashes of marine plants, and in the shells or skeletons of marine animals. (See CORAL, ii. p. 84; SEAWEED, v. p. 212; SPONGE, v. p. 403.) Consequently the action of water in transporting material from the land to the sea, appears to be one of the conditions essential to the existence of marine organisms, and to the formation of submarine deposits, either through their agency or by simple subsidence. (See GEOLOGY, CHEMISTRY OF, ii. 835.)

The amount of sodic and magnesic chlorides carried into the sea by rivers is small, but as these salts probably accumulate in the water, and as the supply from the land, through the agency of water evaporating from the ocean, is continuous, there is some ground for the opinion that the saline contents of sea-water are very gradually augmenting, and indeed that in their present amount they may be altogether the result of the same process continued during long geological periods. In the water of the Baltic and still more in that of the Mediterranean, it has been ascertained with tolerable certainty, that such an augmentation of the saline contents is going on. The evaporation from the Mediterranean, under the influence of hot dry winds from Africa, is so much greater than the supply of fresh water by rivers, that a current of salt water is constantly flowing in from the Atlantic, through the straits of Gibraltar. The water of the Mediterranean consequently contains a larger average amount of saline contents than that of any other sea communicating with the ocean. Moreover, since the amount is greater at considerable depths than it is near the surface, it appears that by the evaporation of the water at the surface, it becomes denser and sinks towards the bottom. In many places the Mediterranean is upwards of 6,000 feet deep, but at the Straits of Gibraltar the depth is only 1,320 feet, so that although there is an outward deep current into the Atlantic, the denser water below that depth cannot flow out. A similar process of concentration is going on in the Dead Sea, and Caspian Sea, in the salt lakes of Russia, and the soda lakes in Egypt and Hungary, which receive either the water of rivers or of springs, and have no outlet for their water but by evaporation.

The vast quantity of material continually being abstracted from the solid mass of the earth by the water of springs, obviously indicates considerable progressive alteration of the rocks from which it is derived. As regards the contents of fresh water, its chief constituents are probably obtained, for the most part, by direct solution. This may also be the case with some kinds of mineral water; but as regards those kinds of mineral water which contain alkaline and ferrous carbonate, &c., together with large amounts of carbonic anhydride, it is more probable that their dissolved contents originate from the chemical alteration of rocks. This is especially the case when the high temperature of the water indicates that it comes from a great depth, where the degree of heat and other conditions obtaining, may be sufficient to determine reactions which do not take place at the surface of the earth. Without having recourse to any theory respecting the former condition of the earth, and its material elements, it is possible to arrive at a probable inference as to the chemical ehanges involved in the production of the various kinds of mineral-water, simply by a consideration of the state in which the substances they contain exist in rocks, or in those minerals which are the most abundant constituents of known rocks, and of the effects which would result under the influence of such conditions as the characters of mineral water testify to the existence of at the seat of their production.

One of the most striking phenomena presented by mineral water is the frequent and abundant occurrence of carbonic anhydride, either dissolved in the water or discharged together with it, and sometimes in enormous quantity, a single spring often yielding annually upwards of a hundred tons, and some artificial springs, like the artesian wells of Neusalzwerk and Nauheim, yielding respectively from 1,300 to 2,000 tons of this gas in the course of the year. Among the gases associated with mineral water, carbonic anhydride not only occurs in the largest amount; but also exercises considerable influence on the character of the water, in many cases, by determining the solution of calcic, magnesic, and ferrous carbonates, &c. From the frequent occurrence of this gas in connection with volcanic phenomena, and the very general distribution of calcic and magnesic carbonates in rocks, it is probable that the action of subterranean heat upon such rocks gives rise to the production of carbonic anhydride, either by direct decomposition, or more probably by determining the reaction of these carbonates with the silica of silicious rocks, in such a manner as to form products which, like lava and basalt, contain both lime and magnesia combined with silica. Carbonic anhydride may also originate from the decomposition of organic remains in rocks, and from their oxidation by reducible substances such as ferric oxide, and it may be to some extent produced by a subterranean process of combustion, either of carbon, or carbonaceous substances by atmospheric oxygen conveyed into the interior of the earth by water. The occurrence of nitrogen together with the carbonic anhydride evolved from springs, and in volcanic districts, gives some probability to the opinion that the carbonic anhydride may originate partly in this way.

But whatever be the precise mode in which the carbonic anhydride associated with mineral water may originate, its abundant existence in solution at great depths, and consequently under great pressure, is beyond doubt. For that reason, a consideration of the action of such a solution upon rocks of the kind which may be supposed to exist at those depths, is of great interest as regards the production of mineral water. Struve found that a number of silicious rocks were decomposed when exposed to the action of water saturated with carbonic anhydride under considerable pressure, and that the substances dissolved by the water almost exactly corresponded with the dissolved contents of various kinds of mineral water. Thus, for instance, in operating upon phonolite in this way, the substance dissolved contained sodic, calcic, and magnesic carbonates and silica, almost in the same relative proportion as the carbonated alkaline water of Bilin. Basalt and felspathic porphyry yielded substances corresponding to the dissolved contents of the Eger, Marienbad, and Töplitz water. It may, therefore, be inferred with considerable probability that the decomposition of such silicates as constitute those rocks, by water containing a large amount of carbonic anhydride, is the source of the alkaline carbonates in mineral water, and to a great extent also of the calcic, magnesic, and ferrous carbonates it contains. Some idea may be formed as to the magnitude of this process of subterranean alteration, from the fact that the mineral water of Vichy alone brings up annually from the interior of the earth about 1,000 tons of sodic carbonate, while the water of the Carlsbad springs brings up at least ten times as much. The occurrence of kaolin, steatite, serpentine, and a variety of similar mineral substances, may be regarded as a phenomenon correlative to such a decomposition as that by which the alkalis or other bases of felspar, augite, or hornblende, are extracted in the production of mineral-water, and those minerals may represent the residual parts of rocks decomposed in this manner during very remote periods. It would be out of place here to enter more fully into the subject of mineral alteration by water containing various substances in solution, than to point out that the conditions under which mineral water comes into contact with rocks at great depths are peculiarly favourable to the production of many of those changes of minerals and rocks which have hitherto been ascribed to imaginary causes, without a sufficient knowledge of their chemical features. (See GEOLOGY, CHEMISTRY OF, ii. 833; PSEUDOMORPHS, iv. 374; and Bischof, Chem. Phys. Geology.)

The *nitrogen* which is so frequently associated with mineral water, either in its gaseous contents, or in the gases discharged with it from springs, does not appear in all cases to consist merely of that atmospheric nitrogen which may be conveyed, in solution by the water, from the surface to the place where it acquires its saline contents, although that may sometimes be the case, especially when the nitrogen is accompanied by oxygen. The proportion of nitrogen to the other gases, and the actual quantity discharged is sometimes so large—as, for instance, at the Bath springs, where it amounts to about 250 cubic feet daily—that there are probably other sources of this gas, such as the slow decomposition of organic remains. Its occurrence has also been referred to an assumed process of subterranean oxidation of metals by atmospheric air, which is supposed to penetrate in some way to great depths in the interior, and in conjunction with the reaction of water on these metals to give rise not only to the phenomena of thermal springs, but also of earthquakes and volcanoes. (See Daubeny, Description of Volcanoes, Earthquakes, and Thermal Springs.—Bischof, Chem. Phys. Geology.—Lecoq, *Les Eaux Minérales.*

The *sulphuretted hydrogen* present in some kinds of mineral-water originates from the reduction of sulphates by carbonaceous substance and the decomposition of the sulphides by carbonic anhydride.

Quality of Water used for economic and technical purposes.

Since natural water is never absolutely pure, it is evident that as regards the water derived from any particular source, its fitness for ordinary use will depend chiefly upon the amount and nature of the substances which may be present in a state of solution, and perhaps also mechanically suspended in the water. For drinking and for many other purposes, water which is perfectly clear and colourless is sensibly preferable to such as is turbid and coloured, in consequence of its containing suspended impurities whether they consist merely of earthy mud, or of minute living organisms. In this respect, spring or well-water, which undergoes a kind of natural filtration, is generally preferable to the water of rivers or lakes, which being fed to a great extent by surface drainage, are therefore the receptacles of much suspended impurity, and generally yield water which is turbid.

So far as dissolved substance is concerned, those kinds of water which contain the smallest amount are generally preferable for most purposes. But the quality of water, as regards its technical and economic applications, is, within certain limits, much more influenced by the chemical nature of the dissolved contents, than by the actual amount. Those kinds of water which contain but a small amount of saline contents, or in which the saline contents, though in large amount, consist chiefly of alkaline salts, are, in ordinary language, termed "soft." Such water dissolves common soap without causing any, or at most but very little, change. On the contrary, water containing calcareous or magnesian salts in solution, decomposes soap, forming with its fatty acids insoluble compounds which separate as a curdy white precipitate. Such water is commonly called "hard," and is more or less so in proportion to the amount of earthy salts it contains. The salts which render water hard are calcic or magnesic carbonates, sulphates, or chlorides, and as the former are held in solution chiefly by carbonic acid, the hardness due to them may be, to a great extent, removed by boiling the water, and by driving off the carbonic acid, rendering the carbonates insoluble. But the hardness due to the sulphates and chlorides is not affected by boiling. Hard water is objectionable for many purposes. Its use for washing involves considerable waste of soap, since the curdy precipitate has no detergent action. For cooking and for various manufacturing purposes also, it is inferior to soft water. When it is used for supplying steam boilers, the insoluble carbonates are deposited as a crust upon the inner surface of the boiler, especially when the water also contains calcic sulphate. This salt is deposited as the water evaporates in a crystalline state, and serves to cement together the particles of carbonate precipitated when the water is first heated.

The total amount of dissolved contents in water suitable for economic and technical purposes rarely exceeds ·5 grm., or at most, 1·0 grm. per litre, and the better kinds of water contain very much less.

The presence of *dissolved organic substance* in water has probably a much greater influence in determining its fitness for dietetic purposes than either the amount or nature of the saline contents of ordinary fresh water. This is especially the case as regards the water of wells or rivers so situated that the drainage or sewage of towns passes into them. When this takes place to any considerable extent, the natural process of purification of river-water, consisting in the oxidation and destruction of the organic substance, is not sufficient to render the water of such streams fit for domestic use near the places where the sewage of large populations, or the drainage of factories, is discharged into them (p. 1018). Water containing ·1 grm. per litre of organic substance would perhaps generally be unfit for drinking, and it may be assumed that wholesome water of good quality rarely contains more than from ·005 to ·01 grm. per litre. However, in districts where peat abounds, water which is sensibly coloured by dissolved organic substance is commonly used for drinking without any deleterious results. Probably the nature of the organic substance in water, its existence in certain conditions, or its capability of promoting the development of organic germs, may be of much greater importance as regards the wholesomeness of the water, than the actual amount of it. Substances resulting from the partial decomposition of effete vegetal or animal refuse are most likely to be directly prejudicial, and also to favour the development of organic germs, especially if they are nitrogenous, and in a state of putrefactive change (FERMENTATION and PUTREFACTION, ii. 623 *et seq* ; INFUSORIA, iii. 269). This probability is at least consistent with the known effects of such substances, and with the still unexplained connection which is believed by some authorities to exist between the prevalence of epidemic disease and the contamination of water, used for domestic purposes, with sewage or some similar impurity. (Frankland, *On the Water Supply of the Metropolis*, Proc. Roy. Inst. of Great Britain.—Simon, *Report of the Medical*

Officer of the Privy Council for 1866.—Letheby, *Report to the Sanitary Committee of the Commissioners of Sewers of the City of London*, 1867, p. 11 *et seq.*, and *Report on the Cholera Epidemic of* 1866.)

The whole subject of the influence of organic substance on the character of water, in a sanitary point of view, is, however, involved in much obscurity; but there can be no doubt that water contaminated with the refuse of towns is in every respect highly objectionable for domestic purposes. Consequently the practice of discharging sewage into rivers, which at a lower part of their course furnish the water-supply of towns, cannot be too strongly deprecated for this reason, and it is scarcely less objectionable as regards the condition of rivers, and their influence on the sanitary state of the districts along their banks. On agricultural grounds, also, the vast quantity of material possessing value as manure, which is wasted by the discharge of sewage into rivers, constitutes another very cogent reason for the discontinuance of this practice, and for the adoption of some means by which the phosphates, alkalis, and ammonia contained in the refuse of towns should be turned to useful account in augmenting the production of crops, and by which at the same time the natural purity of river-water should be so far as possible preserved. (See Excrements, ii. 613; Manure, iii. 842; Urine, v. 964.)

The relative wholesomeness of water intended for domestic use appears to be so intimately connected with the presence of organic substance, that considerably attention has lately been devoted to the methods of estimating its amount and nature. Hitherto the amount of organic substance has been estimated by evaporating the water to dryness and igniting the residue so as to burn off the organic substance, the loss of weight on ignition being taken as representing organic substance. This method, however, apart from the objection of its being indirect, cannot be depended upon, for the following reasons:

1. If the residue is dried at 100° C., before ignition, it may retain water combined chiefly with calcic and magnesic chlorides or sulphates, and a considerable part of the loss on ignition, may be due to this circumstance. A further part may be due to volatilisation of ammoniacal salts, and to the decomposition of magnesic chloride, nitrites, and nitrates.

2. If the residue is dried at from 120° to 130° C. in order to expel water, there is a risk of partially decomposing the organic substance, especially when it is in a putrescent state.

3. In converting the causticised earths into carbonates, after ignition, by means of carbonic anhydride, there may be in some cases a considerable increase of weight.

The method of adding sodic carbonate to the water before evaporating to dryness, so as to decompose ammoniacal salts, and convert calcic and magnesic chlorides and sulphates into carbonates, and to obtain a residue free from water, also gives indefinite results partly for the reasons already given, and because:

4. The organic substance may be decomposed and the products volatilised during the evaporation to dryness.

5. On ignition, certain products of the organic substance may remain in a fixed state of combination in the residue.

The errors arising from one or other of these causes may exceed the whole amount of organic substance in the water; and even if that amount could be estimated with any degree of certainty, the result would not admit of any positive inference as to the character of the water, since the organic substance might be of an entirely harmless nature. (Miller, Chem. Soc. J. xviii. 117.—Frankland, Proc. Roy. Inst. Great Britain.—Wanklyn, Chapman and Smith, Laboratory, i. 98, 114; and Chem. Soc. J. [2] v. 445, 591.)

To meet these defects, the use of potassic permanganate, so as to estimate the quantity of oxygen absorbed by the organic substance in water, has been adopted by some chemists, with the object of arriving at a more direct determination of the character of water as regards this portion of its dissolved contents. As a means of estimating the amount of organic substance, it is however totally untrustworthy, as will be seen from results obtained by Professor Frankland, contained in the table on p. 1024.

These results show that from the great differences which obtain in the behaviour of organic substances with permanganate, it evidently cannot be relied upon for establishing the absence of organic substance. Even its positive indications are not alone conclusive against the character of water, since the reduction may be caused by an organic substance which is quite innocuous. Notwithstanding these facts, however, the permanganate test may afford serviceable indications as to the actual condition of water, especially when the results obtained with it are considered in connection with certain other features of the water in question, for it may reasonably be assumed that, if the presence of putrescent organic substance in water renders it unwholesome, a substance in such a state of chemical tension would be more susceptible of oxidation by permanganate than most of the substances to which Professor Frankland's experiments relate. This special applicability of the permanganate test for indicating the presence

Substance operated upon with permanganate.	1 Amount in 1,000,000 parts of water.	2 Oxygen absorbed in 10 minutes.	3 Oxygen absorbed in 6 hours.	4 Oxygen required for complete oxidation.	Indicated amount of organic substance in 1,000,000 parts of water, calculated from No. 2.	No. 3.

Oxalic acid	30	3·747	3·750	3·8	29·98	30·00
Sodic nitrite	30	6·910	6·913	. .	55·28	55·30

of organic substance in the state most likely to be prejudicial, is not even limited by the fact that the presence of nitrites in water would determine the reduction in the same way as organic substance: for water containing nitrites is very likely to be objectionable (see under), and moreover allowance can always be made for the reduction due to nitrites; so that whenever water causes a considerable reduction of permanganate, there is at least sufficient ground for suspecting it to be unwholesome. Hence Professor Miller and others consider that the permanganate test may render good service as an accessory test, in assisting the judgment as to the salubrity of water, though it is fallacious as a substitute for the method of incineration for estimating the amount of organic substance in water. (Miller, Journ. Chem. Soc. xviii. 117.—R. A. Smith, *Estimation of the Organic Matter in Water with reference especially to Sanitary Purposes*, London, 1865.)

The idea that the deleterious influence of organic substance on the character of water is confined to that portion of it which is nitrogenous and therefore liable to putrefaction, naturally led to the attempt to determine the character of water by estimating the amount of nitrogen in the organic substance present, on the principle of its deleterious influence being proportionate to the amount of nitrogen. (Hofmann and Blyth, *Report on the Chemical Quality of the Supply of Water to the Metropolis*, 1856, p. 5.)

A method of examining water has recently been devised by Professor Frankland upon this basis. The estimation, made in the manner described under the head of WATER, ANALYSIS OF, consists of:

1. The amount of organic carbon in the dissolved contents.
2. The total amount of combined nitrogen.
3. The amount of nitrogen existing as ammonia, nitrites, and nitrates.

The difference between the last two data gives the amount of nitrogen existing in the organic substance of the water, and that is taken to be the measure of the quality of the water, so far as organic substance is concerned. One of the objections to this method appears to be the absence of any distinction either between nitrogenous organic substances which are deleterious, or may become so by putrefaction, and others of a perfectly harmless nature, or between a putrescent substance and one which is only capable of becoming so.

The liability of putrescent organic substance in water to be decomposed, and evolve its nitrogen as ammonia during evaporation to dryness, has been adopted by Professor Wanklyn, in conjunction with Chapman and Smith, as a means of ascertaining the character of water, and of estimating the amount of deleterious organic substance it contains. The decomposition of the organic substance is promoted by adding caustic alkali and potassic permanganate to the water, and the quantity of ammonia given off on distillation is then taken as a measure of the deleterious organic substance in the water. (Chem. Soc. J. [2] v. 445, 591.)

The water of rivers and wells sometimes contains ammoniacal salts, nitrites, and nitrates. Whether these substances are in themselves injurious or not, their presence in water may frequently be regarded as indicative either of sewage contamination, or of some similar objectionable admixture with the water, since they are the products of the decomposition of nitrogenous organic materials (see EREMACAUSIS, ii. 497; NITRATES, iv. 83, 90, 99). If that decomposition is incomplete, they may be accompanied by organic substance in the most objectionable state. The presence of these substances in water is, therefore, always calculated to throw suspicion on its quality. Many of the shallow wells situated in towns, and very often near a churchyard, yield water of this kind which, singularly enough, presents characters both attractive and agreeable. Being clear, sparkling, and cool, with that fresh taste which a small proportion of nitre communicates, such water often holds a high place in popular estimation, which is strengthened by the traditional repute of the wells for yielding good water, acquired probably at a time when they were surrounded by open fields, and not fed with the drainage of densely-populated streets. (See Simon, *Reports on the Sanitary Condition of the City of London*, 1849–50, p. 64; 1852–53, p. 42.—Letheby, *Report on the Quality of the Water from the Pumps and Surface Wells of the City of London*, 1866.—R. A. Smith, *loc. cit.* p. 22.—Wanklyn, Chapman, and Smith, Laboratory, i. 252.)

Sometimes, however, water which is quite beyond any suspicion of sewage-contamination or impurity, contains nitrates—as, for instance, the water obtained from artesian wells in the chalk strata. The origin of the nitric acid in this case is not ascertained, but it has been referred to an oxidation of organic substance, ammonia, or nitrogen effected by the oxygen dissolved in the water, and taking place during the passage of the water through the water-bearing strata. (NITRATES, iv. 83.)

Professor Frankland has adopted the estimation of the amount of nitrogen present in these states of combination, as the measure of the *previous sewage-contamination* of the water—that is to say, of the sewage which has been mixed with the water, and has undergone complete decomposition into its final inorganic products. To the result thus obtained he applies a correction, to compensate for that portion of the nitrogen which might have existed as ammonia and ammonic nitrite or nitrate in rain-water, taking for this purpose the mean value, deduced from the observations of Lawes, Gilbert, and Way, of ·240 pts. nitrogen existing as nitrous and nitric acids in 1,000,000 pts. of rain-water, and ·080, the maximum quantity of nitrogen existing as ammonia in 1,000,000 pts. of river-water taken near the sources of streams. This correction of ·240 + ·080 = ·320, which—upon the assumption that average filtered London sewage contains, in 1,000,000 pts., 100 pts. of combined nitrogen—corresponds to 3,200 pts. sewage in 1,000,000 pts. of water, is probably somewhat too high, and in favour of the quality of the water, since ammonia is almost entirely abstracted from rain-water in percolating through cultivated soil. The water supplied to London from the Thames, during January and February 1868, was found to contain, on the average, ·003395 grm. per litre of nitrogen in the state of ammonia, nitrites, and nitrates, or 3·395 pts. in 1,000,000 pts. of water, so that, according to this view, the amount of previous sewage-contamination would be:—

$$30{,}750 : 3{\cdot}395 - {\cdot}320 \quad = \quad 1{,}000{,}000 : 100.$$

The result thus obtained by analysis presents a very remarkable correspondence with the calculated result obtained in a different manner. Thus the average flow of the Thames, just above the point at which the London water-supply is taken, being estimated at 800,000,000 gallons daily, and the drainage of a population of about 600,000 being discharged into the Thames above that point, at the rate of about 30 gallons per head daily, the sewage-contamination of the water, according to these data, would amount to about 22,500 pts. in 1,000,000 pts. of water.

If any of the nitrogenous organic substance, originating from this sewage, had not undergone complete oxidation, its presence in the water would be indicated by the amount of nitrogen in the organic substance contained in the water. If the nitrogenous organic substance in water could be regarded as originating solely from sewage, and the nitrogen could be accurately estimated, it would be possible to determine the *present sewage-contamination* of river-water. Thus, the amount of organic nitrogen given by Professor Frankland, as existing in the water supplied to London from the Thames during the months of January and February 1868, is, on the average, ·00045 grms. per litre, which would be equivalent to 4,500 pts. of actual sewage in 1,000,000 pts. of water, or nearly ·5 per cent. (*Weekly Returns of the Registrar-General*, xxix. 35, 69). But as this quantity is little above the average apparent error of experiment (p. 1031), such a result may be disregarded. The methods by which these estimations are made, are described under the head of WATER ANALYSIS (p. 1026).

The amount of chlorine in fresh water, existing chiefly in the form of sodic chloride, will often serve, in some degree, to indicate whether it has been contaminated with sewage or other forms of animal refuse, and also, in the case of water containing organic substance, whether that is of vegetal or animal origin. It must be remembered, however, that any inference from the presence of chlorine in water must (as in the case of nitrates) be limited by the circumstance that it is a normal constituent of the contents of most natural water, and that, in certain localities, it exists in larger amount in water than in others. As a rule, water containing as much as ·01 grm. of chlorine per litre may be suspected of being contaminated with drainage. (See R. A. Smith, *On the Examination of Water for Organic Matter*, Proc. Philos. Soc. Manch.)

The wholesomeness of water appears to be intimately connected with its state of aëration. In perfectly aërated water, the ratio of oxygen to nitrogen is as 1 : 2 by volume (pp. 1014, 1017); and as this ratio is liable to be altered by the decomposition of organic substance in the water (p. 1018), the estimation of the gaseous contents of water will often serve, in conjunction with the permanganate test, to indicate the actual character of the water, as regards organic substance. Whenever the oxygen amounts to less than one-third of the nitrogen, and the water also causes a considerable reduction of permanganate, the presence of decomposing organic substance is probable. (Miller, *loc. cit.* p. 124.)

But water which is in a normal state of aëration, and does not cause any great reduction of permanganate, may still contain organic substance, either dissolved or suspended, which is susceptible of putrefaction, and therefore capable of rendering the water unwholesome (Hofmann and Blyth, *loc. cit.* p. 5). Such water, under the influence of warmth and light, often becomes putrid, and evolves stinking gases, or presents a copious development of confervæ and other minute organisms. The capability of water to remain for some days at a temperature of about 22° C., without undergoing such change, is therefore another important point to be observed in reference to the question of wholesomeness. (Angus Smith, *loc. cit.* p. 1.)

River-water is frequently so turbid, from the presence of suspended organic substance, as to be unfit for use without undergoing filtration. This is generally effected on the large scale—sand, gravel, and similar materials being used for the purpose. By this means the amount of organic substance is to some extent reduced, and even the saline contents appear to be partially abstracted.

The most effectual method of purifying water appears to be that proposed by Dr. Clark, of adding lime-water in such proportion as to combine with the free carbonic anhydride, and thus precipitate great part of the calcic carbonate. By this means the water is rendered soft, and a considerable portion of the organic substance is removed. Unfortunately, the removal of the carbonic anhydride renders the water flat and unpalatable, and the vast mass of calcic carbonate produced constitutes a serious difficulty. The addition of alum or aluminic chloride in small amount to the water has also been proposed for separating calcic carbonate and suspended organic substance by means of the basic aluminium salt produced, and then adding sodic carbonate to ensure the separation of all the alumina. The addition of sodic silicate to water intended for the use of factories has been proposed by Buff and Versmann, so as to precipitate the calcium and magnesium as silicates, and render the water soft.

Sea-water is rendered fit for drinking on board vessels by distillation, and afterwards forcing air into the condensed water. (See *Ure's Dictionary of Arts, Manufactures, and Mines*, iii. 985.) B. H. P.

WATER ANALYSIS. The examination of natural water is most frequently required for the purpose of ascertaining its fitness for economic and technical use, sometimes also for ascertaining the character of mineral water employed for medicinal purposes, &c. The mode of operating is much the same in both cases, so far as relates to the estimation of the various constituents of the dissolved contents; but, in reference to water intended for ordinary use, several special methods of examination are adopted for estimating the degree of hardness, amount and nature of the organic substance, &c., which are not employed in the analysis of mineral water.

The specific gravity of water is best ascertained by filling a flask of known capacity (100 to 300 c.c.), and furnished with a long tubular stopper, with the water at a temperature of 15·5° C., and weighing. The specific gravity of fresh water generally differs so little from that of pure water that its determination is not a matter of much importance.

The colour of water should be observed by filling a flat-bottomed glass tube with the water, and looking down through it at a white object, beside a similar tube filled with pure water. The presence of suspended substance and minute vegetal or animal organisms is also to be noted, as well as the smell or taste, both cold and when slightly warmed.

Water is often either alkaline or acid, and to ascertain this it should be tested with very delicate litmus-paper, observing whether any change of colour produced on it, disappears or not when the paper is afterwards exposed to the air. In such cases the reaction may be due to the presence of carbonic anhydride or of ammonia. Water intended for analysis should always be put at once into stoppered glass bottles when collected, and these should be quite filled, and distinctly labelled.

Estimation of Total dissolved Solid Contents.—This is effected by evaporating a known volume of the water—from half a litre to 1 or 2 litres—nearly to dryness in a platinum-basin, which need not be large enough to contain the whole quantity at once, but can be filled up from time to time. For this purpose the water should be perfectly clear; but sometimes the separation of suspended substance cannot well be effected otherwise than by leaving the water for a long time to settle, and then it is best to evaporate the water as it is. Care must be taken to avoid any access of dust or fumes, and to guard against any loss by spirting. Water containing a large amount of gaseous contents must be very carefully heated at first, for this reason. When the water has been reduced to a very small quantity, and the dissolved contents begin to separate, the evaporation is completed in a steam-bath, and the residue thoroughly dried at 100° C., until the weight remains constant.

With mineral-water containing magnesic chloride, bromide, or iodide, which are liable to be partially decomposed during the evaporation, it is advisable to add a known quantity of pure sodic carbonate, just sufficient to render the water alkaline, and to deduct the weight from that of the dry residue. But with fresh water this loss is of comparatively little importance, and it is preferable not to use sodic carbonate, which might cause decomposition of the organic substance. (See p. 1023.)

This result is useful as a control of those obtained in estimating the several constituents of the solid contents. No very close correspondence can be expected, however, especially when the residue is dried only at 100° C., since it may then contain hydrated salts; but this is probably the best temperature to employ generally, and at any rate in the first instance.

Estimation of fixed Mineral Contents.—For this purpose the residue obtained by evaporating the water to dryness, is ignited until all the carbon of the organic substance is burnt off, and the weight noted. As earthy carbonates might be partially decomposed by this treatment, the residue is then to be covered with a saturated solution of carbonic acid, again dried, and heated to about 500° C., this operation being repeated until the weight remains constant. This result, like the previous one, is chiefly useful as a control of the other results of analysis.

Estimation of Suspended Substance.—It is often very difficult to render turbid water clear by filtration, and in such cases it is best to evaporate the water at once with the suspended substance, and to fill a large stoppered bottle of known capacity with the water, leaving it until the suspended substance has subsided; then to draw off the clear water, collect the sediment on a filter, dried and weighed at 100° C., dry it at the same temperature, and weigh, afterwards burning the filter and its contents, and weighing the residue. The weight of the suspended substance dried at 100° is then to be deducted from that of the residue left on evaporation of the water (p. 1026), and after its ignition the weight is to be deducted from that of the ignited residue of evaporation.

Estimation of Hardness.—Clark's method is based upon the fact that when pure water is mixed with a very small quantity of alcoholic solution of soap, and shaken for a few minutes, a froth is produced, which is persistent for some minutes, while, on the contrary, when the water contains calcic or magnesic salts in solution, no such froth is produced until a sufficient quantity of soap-solution has been added to decompose these salts. The quantity of soap-solution requisite to produce the froth in water containing such salts is, moreover, to such an extent proportionate to the amount of these salts in the water, that with a soap-solution of known volumetric value, the degree of hardness is indicated by the quantity requisite to produce the froth in a given quantity of water.

The hardness of water is expressed in degrees, each of which represents ·01 grm. of calcic carbonate, or its equivalent of any other calcic or magnesian salt in the litre of water.

The soap-solution is made by dissolving white curd-soap in alcohol (specific gravity =·92), and its strength is adjusted so that 100 c.c. suffice to produce the froth with 100 c.c. of a solution having 20° of hardness. This solution is prepared by dissolving ·20 grm. of pure calcic carbonate in hydrochloric acid, evaporating the solution to dryness, so as to remove all excess of acid, then dissolving it in pure water, and making up the volume to exactly 1 litre. This standard calcium-solution, of 20° of hardness, is preserved in a well-stoppered bottle. A series of other calcium-standards, varying from one degree upwards, may be made by diluting that solution, in due proportions, with pure water.

The water to be examined is measured with a pipette, guaged to deliver 100 c.c. into a stoppered bottle of about double that capacity; and the soap-solution is added to it from a graduated burette in small successive portions, the water being well shaken in the bottle after each addition. This is continued until a persistent froth appears on the surface of the water. A second experiment is then made comparatively, with the water and the standard solution to which it approximates most closely in hardness.

When the hardness of water exceeds 20°, the indications of the soap-test do not correspond with the amount of calcic and magnesic salts in the water, and in that case it should be diluted with such a volume of pure water, that its hardness is reduced to within 20°, and 100 c.c. of the mixture tested. The degree of hardness found for the mixture is multiplied by 2, 3, or 4, according to the extent to which the water has been diluted.

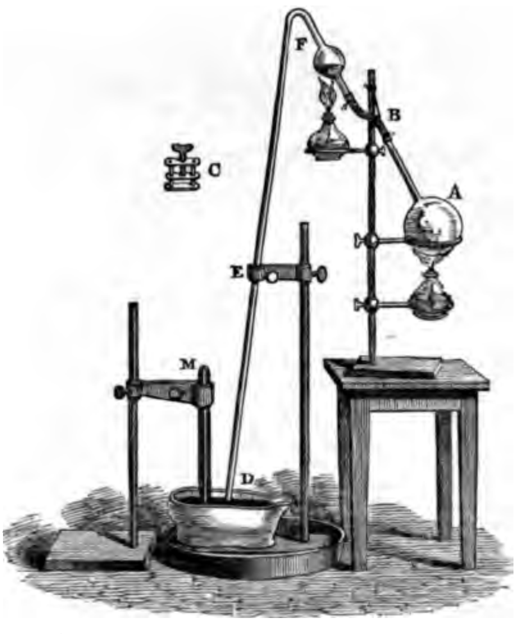
When the water contains any considerable amount of magnesic salts, the indications of the soap-test do not represent the full degree of hardness. It is therefore always necessary, after applying the soap-test, to ascertain whether magnesic salts are present, or their presence may be recognised by the curdy appearance of the water after the experiment. (Campbell, Phil. Mag. xxxvii. 171.)

After estimating the total hardness of water as above, a known quantity of the water should be boiled for an hour in a glass flask with a tube three or four feet long, resting on its neck by a bulb blown at the lower end, to serve for condensing the water-vapour. When the water is cold, some pure water is added, to make up exactly for the loss by evaporation, and the hardness is again estimated by the soap-test. It is generally found to be reduced, after the water has been boiled, in consequence of the precipitation of calcic and magnesic carbonates, originally held in solution by carbonic anhydride.

Estimation of the Carbonates precipitated by Boiling.—For this purpose the precipitate formed in the last experiment may be collected on a weighed filter, washed, dried at 100°, and weighed; any portion of the precipitate adhering to the flask may be weighed by drying the flask, weighing it, and deducting the weight of the flask. The whole of the precipitate is then dissolved by hydrochloric acid, and the calcium and the magnesium separated and estimated (iii. 753; i. 717). This precipitate may contain iron, manganese, phosphoric acid, silica, and sulphuric acid, which should be tested for and, if requisite, estimated. Sometimes, as in the analysis of fresh water, it is desirable to evaporate the water to one-half or one-fourth, before collecting the precipitate.

Estimation of the Gaseous Contents.—For this purpose a globular glass flask A (*fig.* 822) of about half a litre or a litre capacity, and having a strong piece of vulcanised caoutchouc tube B tightly fitted to its neck, is quite filled with the water to be examined, and then closed by means of a brass screw-clamp C, which presses the sides of the tube close together. The other end of the caoutchouc tube is then tightly connected with the bent glass tube D E F, having a bulb at F. This bulb is partly filled with water which is made to boil briskly, while the clamp C is still closed, and the delivery end of the tube D dips into mercury, so as to drive the air out of the tube. After the boiling has been continued for 10 or 15 minutes, until no more air escapes at D, the jar M is filled with mercury, and placed over the delivery end of the tube. The clamp C is then removed, and heat applied to the flask A, until the water boils. The boiling must be steadily kept up for fully an hour, and at last the water is made to boil briskly for a few minutes, so as to fill the delivery-tube with steam, and drive all the gas discharged from the water out of the tube into the jar M. The gas is then measured and analysed in the usual way. (ANALYSIS OF GASES, i. 268.)

Fig. 822.



Estimation of Organic Substance.—For the reasons already stated (at p. 1023), the loss of weight, caused by igniting the residue left on evaporating water to dryness, affords no adequate indication of the amount of organic substance; but it is often useful to observe the effect of heat upon this residue when igniting it (p. 1027), as a means of judging as to the amount and nature of the organic substance present, and also as to the presence of nitrates. Several methods have been proposed for the purpose of examining water for organic substance, but the one which has been most used is based upon the characteristically-marked oxidising action of potassic permanganate. Oxalic acid, dissolved in water, acidulated with sulphuric acid, is readily and completely oxidised by permanganate, yielding carbonic anhydride and water, as follows:

$$\left.\begin{matrix} \mathrm{Mn^2K^2O^8} \\ \mathrm{3\,SH^2O^4} \end{matrix}\right\} = \left\{\begin{matrix} \left.\begin{matrix}\mathrm{2\,SMnO^4} \\ \mathrm{SK^2O^4}\end{matrix}\right\} + \mathrm{3H^2O}. \\ \left.\begin{matrix} \mathrm{5\,O}\quad (80) \\ \mathrm{5\,C^2H^2O^4}\;(450)\end{matrix}\right\} = \begin{matrix}\mathrm{5\,H^2O} \\ \mathrm{10\,CO^2}.\end{matrix}\end{matrix}\right.$$

In like manner, when a few drops of a weak solution of permanganate are added to water containing organic substance and acidulated with sulphuric or hydrochloric acid, the permanganate yields oxygen to the organic substance, and the violet colour disappears. By testing the water with a permanganate-solution of known strength, it is therefore possible to ascertain how much oxygen the organic substance it contains may be capable of abstracting from permanganate.

The permanganate-solution for testing water should be of such strength that 1 c.c. will be capable of yielding exactly ·0001 grm. of oxygen (= ·0003955 crystallised permanganate). Its strength should be adjusted, immediately before using it, by means of a freshly-prepared solution of crystallised oxalic acid containing ·7875 grm. per litre. 100 c. c. of this solution, warmed with some dilute hydrochloric or sulphuric acid, should decolorise exactly 100 c.c. of the permanganate-solution.

In applying the test, a litre of the water is mixed with acid in a glass flask, and the permanganate added from a graduated burette, in small successive portions, until the water retains a very faint violet tinge, the rate of decoloration being noted meanwhile. It is then left for some minutes, and if the colour disappears, a further quantity is added, the observation being continued in this way for two or three hours or more. When the colour remains unaltered for half an hour, the volume of permanganate-solution, read off in cubic centimetres, with a small deduction for the portion which has remained unaltered, gives the quantity of oxygen absorbed, in tenths of a milligramme per litre of water. By operating in this way, some judgment may be formed as to the state of the organic substance, or some portion of it, from the rate of decoloration. (R. A. Smith, *Estimation of Organic Substance in Water*, p. 7.)

The decoloration produced during the first five or ten minutes, may be taken to represent putrescent or readily oxidisable organic substance, regard being had to the possible presence of nitrites; and a portion of the organic substance is generally found to require a much longer time for oxidation—often as much as 24 hours.

The test may also be applied by adding at once a measured excess of the permanganate-solution to the water, and leaving it for three hours, then adding a small quantity of potassic iodide-solution with some starch-paste, and estimating the quantity of iodine liberated by the excess of permanganate, with a standard solution of disodic hyposulphite containing 1 grm. of the salt per litre. The quantity of this solution required to destroy the blue tint must be read off the instant that colour disappears, as it returns after some time. The difference in cubic centimetres between the permanganate-solution added, and the hyposulphite-solution used, gives the volume of permanganate decolorised by the organic substance of the water. (Miller, Chem. Soc. J. xviii. 117.)

If the water under examination should contain nitrites, they would decolorise permanganate in the same way as organic substance; but their action is so very much more rapid than that of organic substance, that the decoloration due to them may be estimated approximatively by this difference, or still better as directed at p. 1033. For each ·001 grm. per litre of nitrous acid (NO^2), ·000348 oxygen, or 34·78 c.c. of permanganate-solution, is requisite.

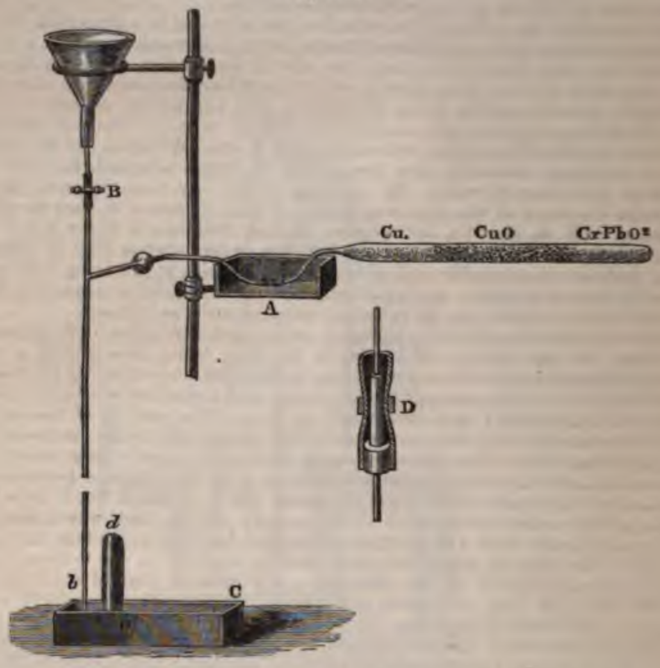
The principal defect of the permanganate test is, that it affords no certain means of distinguishing between harmless organic substance and that which may be deleterious, except in so far as putrescent substances would probably be oxidised by the permanganate most readily and most rapidly. Nor does it afford any means of distinguishing nitrogenous organic substance, which is considered to be the most prejudicial to the character of water for domestic use.

With the view of superseding the permanganate test, it has been suggested, by Frankland and Armstrong (Chem. Soc. J. xxi. 77, *et seq.*), that the carbon and nitrogen of the organic substance may be estimated by operating upon the water residue, much in the same way as the analysis of organic substances is made (i. 226 *et seq.*).

For this purpose, 1 litre of the fresh water is mixed with 30 c.c. of a fresh saturated solution of sulphurous acid, and boiled for two or three minutes. By this treatment, the carbonates are completely decomposed, and the carbonic acid expelled. Unless the water contains a considerable amount of carbonates, 2 grms. of sodic sulphite is also to be added, for ensuring the saturation of the sulphuric acids afterwards produced during the evaporation of the water to dryness. The nitrites and nitrates in the water are also decomposed, and when there is a minute quantity of iron or phosphoric acid present, every trace of nitrogen existing in those forms is separated. To ensure this result, however, it is advisable to add a few drops of ferric chloride solution to the water before evaporating it. The residue obtained from a solution of ·1 grm. potassic nitrate (=·014 grm. N) and ·1 grm. sodic chloride in pure water, treated as above described, gave, on combustion, ·00259 grm. of nitrogen; but the residues of similar solutions, to which a drop of ferric chloride had been added, gave no trace of nitrogen on combustion. Three drops of ferric chloride solution removed all trace of nitrates from half a litre of water containing 24·66 parts of nitrogen as nitrates and nitrites, in 1,000,000 pts.

After evaporating the water to dryness, at 100° C., the dry residue is mixed with a few grammes of plumbic chromate, and the whole transferred, in the usual way (i. 232), to a tube 16 inches long and sealed at one end. The tube is then charged with some granulated cupric oxide, and with bright copper turnings for about 3 inches of its length at the front part, and the open end drawn out before the blowpipe and bent downwards, so that it can be connected with a Sprengel exhaustion-pump by a piece of caoutchouc tube, and the connection immersed in a small vessel of water (as shown at A, *fig.* 823). The front part of the combustion-tube is then made hot, and the pump worked for five or ten minutes, until the air in the tube is as perfectly exhausted as possible. The calibre of the pump-tube should be 1 millimetre, and it is advisable to allow the mercury to flow very slowly, until the exhaustion is nearly complete, when a rapid stream is necessary to remove the last portion of air.

Fig. 823.



To prevent any leakage of atmospheric air into the pump, the caoutchouc pinchcock at B should be enclosed in a wide piece of vulcanised tube, and the clamp placed outside this, while the annular space between the two tubes is filled with glycerin, so that the pinchcock is entirely immersed in this liquid. With this arrangement, which is shown on a larger scale at D, the vacuum remains perfect for several days.

A tube *d*, filled with mercury, is then placed over the bent end *b*, of the pump in the mercury trough C, to collect the gaseous products; and the combustion is conducted in the usual way (i. 233), care being taken that it proceeds very slowly at first, otherwise a small quantity of carbonic oxide might be formed. The operation usually lasts nearly an hour, and at its conclusion no gas will have passed into the tube *d*, unless the water residue contained much organic substance. The pump is then set to work again for five or ten minutes, to transfer the gas into the tube *d*. This gas, consisting of carbonic anhydride, nitric oxide, and nitrogen, is analysed in the usual way (ANALYSIS OF GASES, i. 268). By this method, ·0000005 grm. carbon, and ·000001 grm. nitrogen, are stated to be distinctly measurable quantities.

The quantities of gases thus obtained represent the carbon and nitrogen of the organic substance contained in a litre of the water, and any nitrogen present in the water as ammonia. As the amount of ammonia is estimated separately, the quantity of nitrogen corresponding to it can be deducted from the total quantity.

The accuracy of the results obtained by this method evidently depends, in a great measure, upon the perfect removal of air from the tube by the Sprengel pump; and to ascertain the extent to which this can be done, two combustions were made with ·01 grm. sugar, and the quantity of nitrogen found was ·019 c.c., and ·013 c.c. at 0° C. and 760 mm. pressure, corresponding to ·000024 and ·000016 grm. of nitrogen, or ·024 and ·016 parts in 1,000,000 parts of water.

The correction to be made for the error thus arising from imperfect exhaustion, is comprised in another correction for errors of manipulation and apparatus, the amount of which is to be ascertained by making several blank experiments, in which a litre of pure water mixed with 15 c. c. of sulphurous acid solution, and about 1 grm. of recently ignited sodic chloride, is evaporated to dryness, and a combustion made with the residue, as above described. The mean quantities of carbon and nitrogen found in these experiments, are to be deducted from those obtained in the combustion of water residues. In order to reduce these errors to a minimum, it is of the utmost importance to ensure the purity of the cupric oxide and plumbic chromate, &c. used in the operation, and to guard against any access of dust or organic substance to them, or to the water, during any stage of the operation.

To show the extent to which this method may be depended upon for estimating the minute quantities of carbon and nitrogen in the organic substances likely to be present in a litre of water, several experiments were made with pure water, mixed with carbonates and known quantities of sugar or urea, varying from ·01 to ·035 grm. per litre. The results obtained for carbon differed from the calculated quantities to the extent of from 1·28 to 15 per cent., the average apparent error being ·00043 grm. on the carbon; the largest difference representing 1·22, and the smallest ·06 parts of carbon in 1,000,000 parts of water, or 2·022 and ·3 parts of the organic substance. The results obtained for nitrogen differed from the calculated quantities to the extent of from ·64 to 5·83 per cent., and in one instance 25·1 per cent., the average apparent error being ·00035 grm. on the nitrogen; the largest difference representing 1·21 and ·55, and the smallest ·03 parts of nitrogen in 1,000,000 parts of water, or 2·59, 1·17, and ·13 parts of the organic substance. The quantities of nitrogen operated upon in these experiments were much larger than those found in water of moderate quality. With mixtures of pure water, calcic carbonate, and sewage, in three different proportions, the following results were obtained:

Sewage	100,000	10,000	1,000
Water	900,000	990,000	999,000
In 1,000,000 parts.			
Organic Carbon	3·02	·33	·05
„ Nitrogen, and Nitrogen of Ammonia	3·30	·33	·04

The method proposed by **Wanklyn** in conjunction with **Chapman** and **Smith** (Chem. Soc. J. xx. 445, 591), relates especially to the nitrogenous organic substance in water. It does not, any more than the combustion or the permanganate method, afford the means of estimating the actual amount of this substance; but it has the advantage of being directly applicable to the water itself, and of furnishing results in a very short time without much trouble, so that, in regard to nitrogenous organic substance, it corresponds to the soap-test as regards hardness. This method of testing the quality of water is based upon the fact that albumin and the nitrogenous substances sometimes present in water, yield a considerable portion of their nitrogen in the form of ammonia when heated with a strongly alkaline solution of potassic permanganate. For this purpose, it is necessary in the first place to separate the ammonia existing as such in the water, and to decompose any urea that may be present. The operation is conducted as follows:—

I. A litre of the water is mixed with about 2 grms. sodic carbonate in a retort, and rapidly distilled, until the distillate, collected in separate fractions of 100 c. c., no longer gives any indication of ammonia with Nessler's test. With ordinarily good water, this generally happens when about 300 c. c. has passed over, and then the distillation is stopped. The quantity of ammonia in the first 100 c.c. may be estimated as ammonia actually present in the water, and that in the remainder of the distillate as representing urea, or the whole may be estimated together (see under). The decomposition of urea by boiling with sodic carbonate appears to depend very much on the presence of such impurities as generally accompany it in urine or sewage; pure urea is very slowly and imperfectly decomposed (*loc. cit.* p. 594).

II. The portion of the water remaining in the retort is then mixed with 20 c.c. of caustic potash solution—equal parts potash and water—and again distilled. When 300 c. c. has passed over, the distillation is stopped, and the ammonia in the distillate estimated by the Nessler test.

III. About ·3 grms. of crystallised potassic permanganate is then added to the contents of the retort, and, if requisite, 100 or 200 c.c. of pure water, the distillation recommenced, and continued until 300 c.c. has come over. The ammonia in this distillate is estimated as before, and taken, together with that in the second distillate, as representing about two-thirds of the nitrogen in the albuminoïd substance present in the litre of water.

Experiments made with solutions containing from 7 to 42 pts. fresh white of egg, or from 1 to 6 pts. of dry white of egg in 1,000,000 pts. of pure water, gave, by this treatment, quantities of ammonia which corresponded with the quantities of white of egg to within 5 per cent., the average absolute error being ·000004 grm. on the calculated quantity of ammonia obtainable.

Estimation of Ammonia.—A litre of the water is mixed with 2 grms. sodic carbonate, and distilled until 100 or 200 c.c. has passed over, and the ammonia estimated in the distillate by Nessler's method.

The test-liquid for this purpose is prepared by mixing a concentrated solution of mercuric chloride with a solution of potassic iodide in 4 parts of water, until the mercuric iodide formed ceases to be dissolved on stirring the mixture; then adding potash-solution—equal parts potash and water—until the potash amounts to six times as much as the mercuric chloride, and diluting with water until the liquid contains about 25 grammes per litre of mercuric chloride. After a day or two, the liquid becomes clear and colourless, and it is then decanted off for use.

About 3 c.c. of this test-liquid is added to one-half of the distillate from the water, in a tall narrow glass jar, and if it contains no ammonia no alteration of colour is produced; but if ammonia is present, to the extent of more than ·002 per litre, the water acquires a yellowish tinge, which is deeper in proportion to the quantity of ammonia, and when this is large a precipitate is produced.

The quantity of ammonia in the distillate may be estimated, approximately, by the depth of colour, and afterwards more accurately by comparing the depth of colour produced in the other half of the distillate with that produced in an *equal volume* of a solution containing a known quantity of ammonia, as nearly as can be judged equal to that in the distillate, on adding to each *equal quantities* of the test-solution. and repeating this comparative observation with different quantities of ammonia, until the tint of the standard solution coincides with that of the distillate. For this purpose a standard solution of ammonic chloride, containing ·317 grm. (= ·1 grm. NH^3) per litre, is prepared, and kept for making the solutions for comparison, by mixing a measured quantity with pure water to the volume of 100 c.c.

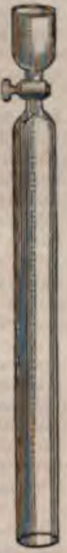
By this means very small quantities of ammonia may be estimated to within about 5 per cent. of the actual quantity. When the amount of ammonia in the water exceeds ·001 grm. per litre, the distillate must be diluted with water free from ammonia before applying the test; or the ammonia may be estimated with a standard solution of sulphuric acid (i. 190, 261).

Estimation of Nitrates and Nitrites.—The presence of nitrates or nitrites in water may be indicated by the deflagration of the residue left on evaporation, when it is ignited; or one of the tests for nitric or nitrous acids (described in iv. 83, 85) may be applied to a portion of the water evaporated to a tenth of its volume, and filtered. The amount of nitrous acid may be approximately estimated by means of permanganate-solution, especially if there is no organic substance present, or if it can be separated by mixing the water, before evaporating it, with a few drops of aluminic chloride, and then with sodic carbonate, and filtering. Each cubic centimetre of the permanganate decolorised by nitrates, represents ·0002875 grm. NO^2. The results thus obtained will always be somewhat uncertain.

Professor Frankland estimates the total amount of nitrogen present in the form of nitrates and nitrites by a method based on the reduction of the acids by mercury

(**Crum**, Phil. Mag. xxx. 426). A litre or half a litre of the water is evaporated to a small bulk, mixed with a very slight excess of argentic sulphate to convert any chlorides into sulphates, and filtered. When the water contains nitrites, they should be converted into nitrates before the evaporation, by means of permanganate-solution. The filtered liquid is then evaporated in a small beaker, to about 2 or 3 c.c., and transferred to a glass tube open at one end, and furnished with a stopcock and funnel-shaped mouth at the other end, as shown in *fig.* 824. This tube is first filled with mercury in the mercury-trough, and after the water-residue has been poured in, the beaker is rinsed first with water, and then with rather more than 3 c.c. sulphuric acid, which is also poured into the tube, care begin taken to avoid the admission of any air below the stopcock. This is then closed, and the lower end of the tube is closed, while immersed in the mercury-trough, by the thumb; so that, on removing the tube from the trough, the contents of the tube may be shaken well together, while an unbroken column of mercury, at least an inch long, remains between the acid liquid and the thumb. The evolution of nitric oxide soon begins to exert a pressure within the tube, which should be resisted; and within five minutes, when the reaction would be at an end, the gas is transferred under mercury to a suitable measuring apparatus, and the volume determined in the usual way.

Fig. 824.



To ascertain the degree of accuracy of this method, two experiments were made with ·02 and ·01 grm. of potassic nitrate; these gave quantities of nitrogen, which were ·000125 and ·000038 grm. in excess of the calculated quantities. It was ascertained that urea, creatine, uric and hippuric acid, gave no trace of gas when agitated with mercury and concentrated sulphuric acid.

Estimation of Sulphuric Acid.—A litre of the water is evaporated in a beaker to one-fourth or less, then acidulated with hydrochloric acid to dissolve any precipitate, baric chloride solution added in excess, and the precipitate collected as described at p. 537.

Estimation of Chlorine.—A litre or more of the water is evaporated to about 200 c.c., acidulated with nitric acid, and the chlorine estimated as argentic chloride, as described in i. 903.

With water containing large amounts of sulphates or chlorides, it is not necessary to operate on so much as a litre, or to evaporate the water. This may be judged of by the qualitative examination of the water.

Estimation of Carbonic Acid.—That portion of the carbonic acid which corresponds to the neutral carbonates in the water, may be estimated by evaporating a quantity of the water nearly to dryness, in a small glass flask, and treating the residue as described under the heads ACIDIMETRY and ALKALIMETRY (i. 38 and 119).

The total amount of carbonic acid in mineral-water may also be estimated by mixing a measured quantity of the water with about one-fifth of a perfectly clear solution of baric chloride and ammonia in a well-stoppered bottle, and leaving it for some days until the precipitate has perfectly subsided. The clear liquid is then decanted off, as much as possible without access of air, the bottle filled with warm water free from carbonic acid, closed, and left till the precipitate has subsided; the clear liquid is then decanted, and this operation repeated until the precipitate is sufficiently washed. It is then collected on a filter, dried, ignited, and weighed, care being taken that any portion causticised during the burning of the filter is reconverted into carbonate. The amount of carbonic acid is then estimated, either in the whole or in a portion of this precipitate, with dilute nitric acid, in an apparatus similar to *fig.* 6 (i. 119); but having a bulb blown on the tube *a b* at the upper end, while the lower end reaches only half-way into the flask, and is contracted, so that the acid contained in the bulb at *b* cannot flow out into the flask, while the wax or caoutchouc plug is in its place. After weighing the flask, the plug is loosened for an instant to let out some acid, and this is repeated from time to time until the carbonate is completely decomposed. The flask A is then placed in hot water, suction applied very gently to the tube *d*, while the plug is loosened at the same moment, and air is drawn through until the carbonic acid is entirely removed, when the apparatus is again weighed.

Estimation of Sulphuretted Hydrogen.—A litre or more of the water, acidulated with acetic acid, is mixed with some thin starch-paste in a large flask, and a solution of iodine in potassic iodide added from a graduated burette, until a persistent blue coloration is produced. The iodine-solution used for this purpose should contain ·7938 grm. per litre, and then each cubic centimetre represents ·0001 grm. sulphur.

Estimation of Iodine and Bromine.—The residue obtained by evaporating 10 or 20 litres of the water in a platinum-basin, is rubbed with alcohol of 90 per cent. until all the soluble portion is extracted. The solution is then filtered and evaporated to dryness. In the residue, iodine is estimated with palladic chloride as directed in iii. 296, and bromine as directed in i. 678.

The portion of the saline residue which is not dissolved by alcohol, may be used for estimating silica, aluminium, manganese, barium, strontium, phosphoric acid, lithium, fluorine, &c., by the methods described under these several heads. Cæsium and rubidium are tested for, and estimated, as described in i. 1113, and at p. 130 of this volume.

Boric acid is tested for by evaporating a quantity of the water to a small bulk with sodic carbonate in excess, filtering, and nearly saturating the filtrate with hydrochloric acid, then evaporating almost to dryness, separating sodic chloride by filtration, and testing the filtrate as described in i. 639.

Estimation of Silica.—The residue left after ignition of the solid contents (p. 1027), is moistened with water, mixed with excess of hydrochloric acid, and the silica separated as described at p. 245. Sometimes it is preferable to mix a litre or more of the water with a moderate excess of hydrochloric acid, and evaporate it to dryness for the estimation of silica.

Estimation of Aluminium, Iron, Manganese, and Phosphoric Acid.—The filtrate from the silica is evaporated to a small bulk in a beaker; then mixed with ammonic chloride, a slight excess of ammonia free from carbonate, and some ammonic sulphide; and kept for some hours at a gentle heat in a well covered beaker. The precipitate is collected on a filter, and washed, out of contact with air, with water containing some ammonic sulphide. The filtrate is set aside, and the precipitate, which may contain alumina, ferrous and manganous sulphides, and phosphoric acid, is either dried, ignited, and weighed, if the quantity is very small; or it is dissolved in hydrochloric acid, and the solution is boiled with a few drops of nitric acid to oxidise the sulphides. When manganese is present in any considerable amount, the solution is nearly neutralised with sodic carbonate, mixed with barytic carbonate in excess, and left for some hours in the cold. The precipitate is collected on a filter and washed, dissolved in hydrochloric acid, the barium separated with sulphuric acid, and the aluminium and iron separated as directed under IRON (iii. 387). The filtrate from the precipitate produced by barium-carbonate will contain the manganese: the barium is separated by sulphuric acid; manganese precipitated by ammonia and ammonic sulphide; and the washed precipitate is dried, ignited, and weighed. The filtrate should be tested for calcium and magnesium. When manganese is absent, or there is only a minute trace, the solution of ferrous sulphide may be at once treated with potash to separate iron and aluminium.

Estimation of Calcium and Magnesium.—The filtrate from alumina and the sulphides is mixed with a slight excess of ammonic oxalate, and the calcium estimated as directed in i. 717. Magnesium is separated from the alkaline salts with mercuric oxide as directed in iii. 753.

Estimation of Sodium and Potassium.—The filtrate from the magnesia is evaporated to dryness, and the residue weighed, then dissolved in water, and tested for sulphuric acid by adding to a portion of the liquid a few drops of alcoholic solution of strontic chloride, and some alcohol. If no precipitate appears, sulphuric acid is not present, and potassium is then separated and estimated with platinic chloride (iv. 699). If sulphuric acid is present, add some alcoholic solution of strontic chloride and some alcohol to the solution, and let it stand for some time, then collect the strontic sulphate on a filter, wash with weak alcohol, dry, ignite, and weigh. Potassium is then estimated in the filtrate with platinic chloride. By deducting from the total weight of the alkaline salts the weights of the potassic chloride and of the sodic sulphate corresponding to the sulphuric acid obtained as strontic sulphate, the quantity of sodic chloride is ascertained, and the total quantity of sodium may be calculated from these data. (See Fresenius, *Quantitative Analysis.*)

Potassium and sodium may also be estimated by evaporating a separate portion of the water to a small bulk, precipitating sulphuric acid with baric chloride, and magnesia with baryta-water, filtering, and then precipitating the excess of calcium and barium by ammonic carbonate, again filtering, and evaporating the filtrate to dryness. The residue is ignited, and dissolved in water; and when the calcium and magnesium are perfectly separated, the potassium is estimated by means of platinic chloride.

Statement of the Results of Water Analyses.—In stating the results obtained in the analysis of the contents of fresh or mineral-water, it has been customary to allocate the several acid and basic substances in various forms of combination, and, in a manner which is very much matter of individual fancy, to assume the existence in the water of certain of the salts which those substances are capable of forming. It may sometimes happen, therefore, that the statement of the same analytical results obtained by two chemists in the analysis of any particular water will, in this way, present, at first sight, an apparent diversity, which would be perplexing to those who do not understand the reason of the difference. The possibility of comparing the results of water-analyses is one of the most important requisites for all practical purposes for which they are useful. For such purposes it is of much less consequence whether certain portions of magnesium, calcium, and sodium present in water be represented as calcic and magnesic chlorides and sodic sulphate, or whether they be represented as calcic and magnesic sulphates and sodic chloride, than to be able to perceive at a glance whether, in reference to other analyses, the total amounts of the several substances present are the same or different. As regards the practical utility of such analyses, it would therefore seem desirable to avoid all hypothesis in stating their results, and to render these statements strictly comparable one with the other. This may easily be done. Thus, for instance, in the case of water containing calcic, magnesic, and sodic salts which are chlorides, sulphates, and carbonates, the simplest mode of stating the analytical results is to give the respective amounts of calcium, magnesium, sodium, chlorine, and, in the case of oxysalts, those portions of them which are equivalent to chlorine—as, for instance, sulphuric acid (SO^4) and carbonic acid (CO^3). The analyses quoted in this article are therefore stated in this manner.

The amounts of the several constituents of the solid contents are, in the case of fresh spring- and river-water, expressed as parts by weight in 1,000,000 pts. by weight of water. These data, which are in most instances sufficiently minute, are easily convertible in such form, as to correspond either with the metric system of weights and measures, or with that used in this country. Thus, for instance, in reference to fresh-water—the density of which does not differ from that of pure water to such an extent as to require notice, the litre being 1,000 grms.—these data represent milligrammes per litre of water, or grammes per cubic metre. The gallon being 10 pounds, they also represent pounds per 100,000 gallons. Thus the total solid contents of the Witley Spring-water (Table I.) amount to ·076 grm. per litre, the calcium to ·008, the magnesium to ·002 per litre, and so on, the fraction in this case being disregarded. These proportions are the same as 76, 8, and 2 grms. per cubic metre, or 76, 8, and 2 pounds per 100,000 gallons.

The data given in the tables may also be expressed as grains per gallon by multiplying with ·07. Thus the solid contents of the Witley Spring-water amount to $76 \times \cdot 07 = 5\cdot 32$ grains per gallon, the calcium to $8 \times \cdot 07 = \cdot 56$, and the magnesium to $2 \times \cdot 07 = \cdot 14$ grains per gallon. The numbers representing hardness are, in like manner, convertible into degrees of Clarke's scale by multiplying with ·7.

The data given in the table for the gaseous contents represent cubic centimetres per litre in the case of fresh spring- and river-water at the ordinary temperature of the water, and in the case of mineral-water at 0° C. and a pressure of 760 mm. These data are convertible into cubic inches per gallon, by dividing with 3·738. B. H. P.

WAVELLITE. Native phosphate of alumina, containing $3Al^2O^3.2P^2O^5.12H^2O$. (See Phosphates, iv. 551.)

WAX. This term, originally restricted to beeswax, is now extended to a class of bodies of similar character, partly of animal, partly of vegetable origin. Only a few of them have been accurately investigated. They are compounds containing but a small proportion of oxygen, and consisting of the higher members of the series of fatty acids, $C^nH^{2n}O^2$, partly free, partly in combination with alcohol-radicles; but they differ from the fats in not containing glyceryl. They are more or less hard at ordinary temperatures, softer when warmed, and melt below 100°; are insoluble in water, sparingly soluble or insoluble in alcohol, soluble in ether, volatile and fixed oils, carbonic disulphide, chloroform, &c. They are not volatile without decomposition, and burn with a bright flame when heated in the air. They are not easily saponified by boiling with potash-ley, more easily by fusion with solid potash.

1. *Animal Wax.*

The only waxes known with certainty to be of animal origin are—common beeswax; Andaquies wax (i. 291), the produce of a peculiar kind of bee found near the Oronoco and Amazon rivers; and spermaceti (p. 397). Chinese wax, or Pela, is supposed, by some authorities, to be a secretion-product of an insect, like beeswax, but it is more generally regarded as a plant-wax, exuding from *Ligustrum lucidium* and other trees, when punctured by an insect.

Beeswax. *Ordinary Wax. Cera.*—This is the substance with which bees build their cells: it was formerly supposed that the bees extracted it ready-formed from plants; but direct experiments have shown that bees fed upon pure sugar continue to produce wax, which must therefore be regarded as a true animal secretion.

Beeswax, at ordinary temperatures, is tough and solid; it has a yellow colour, a peculiar odour, and unctuous feel. When exposed, in thin shreds, to the air and sunshine, it becomes bleached, and somewhat less fusible. It may also be bleached by means of nitric acid. Chlorine likewise bleaches it, but, at the same time, forms a substitution-product, so that when candles made of wax thus bleached are burned, they give off irritating vapours of hydrochloric acid. According to A. Smith, wax may also be bleached by means of potassic bichromate and sulphuric acid.

Bleached wax contains, according to Lewy's analysis, 80·2 per cent. carbon, 13·4 hydrogen, and 6·4 oxygen. It is a mixture of three different substances, which may be separated from one another by alcohol, viz.—1. Myricin (iii. 1069), insoluble in boiling alcohol, and consisting chiefly of myricic palmitate, $C^{16}H^{31}(C^{30}H^{61})O^2$;—2. Cerotic acid, $C^{27}H^{54}O^2$ (i. 836, formerly called cerin, when obtained only in an impure state), which is dissolved by boiling alcohol, but crystallises out on cooling;—3. Cerolein (i. 836), which remains dissolved in the cold alcoholic liquid.

Beeswax is decomposed by dry distillation, giving off, first, a small quantity of water containing acetic acid, and, according to Polex, propionic acid; then a product which forms, on cooling, a white buttery mass, called wax-butter, or *Butyrum ceræ*, afterwards a more and more liquid oil, called wax-oil, still retaining a small quantity of solid matter; and finally leaves a carbonaceous mass. No acrolein is given off, but permanent gases, chiefly carbonic anhydride and ethylene, are evolved during the whole process of distillation. (Ettling.)

Wax-butter, purified by pressure from adhering oil, is mainly composed of solid hydrocarbons, cerotene, $C^{27}H^{54}$, and melissene, $C^{30}H^{60}$, together with palmitic acid. The liquid oil, when purified by rectification, consists chiefly of hydrocarbons, C^nH^{2n}; it has a specific gravity of 0·750 at 11°, and boils at 137°.

Wax, when distilled with lime, yields nearly the same products as when distilled alone. It is but slowly and incompletely saponified by potash-ley, which unites, in the first instance, with the cerotic acid; after prolonged boiling, a kind of soap is formed, which floats on water, and, when neutralised with an acid, yields myricin.

Nitric acid acts upon wax, even at a gentle heat, converting it into an oily mass, which contains pimelic, adipic, and lipic acids, and by prolonged boiling with nitric acid, yields succinic acid.—Strong *sulphuric acid* dissolves wax at 60°, the mass solidifying as it cools; at higher temperatures, carbonisation takes place.—*Chlorine* decomposes melted wax, forming chlorinated products.

2. *Vegetable Wax.*

Wax is very widely diffused in the vegetable kingdom, occurring frequently as a coating on various parts of plants—as stalks, leaves, fruits, &c.

Several of the more important plant-waxes have been already described in their alphabetical places—viz., carnauba-wax (i. 805), cork-wax or cerin (i. 837), pine-wax or ceropic acid (i. 836), sugarcane-wax or cerosin (i. 836), myrtle-wax or myrica-tallow (iii. 1069), ocuba-wax (iv. 173), and palm-wax (iv. 337).

Chinese wax, or Pela, also called *vegetable insect-wax*, or *vegetable spermaceti*, is generally supposed to be produced on certain trees by the puncture of a species of *Coccus*. It envelopes the branches as a soft white coating, about a line in thicknes, and is separated by fusion in boiling water. It consists almost wholly of cerotylic cerotate $C^{27}H^{53}(C^{27}H^{55})O^2$, contaminated only with small quantities of fatty substances. Its physical properties and most of its reactions have been already described (i. 837). When it is boiled for some time with 4 or 5 vols. of nitric acid, of specific gravity 1·40, a liquid distils over, containing butyric, œnanthylic, and caprylic acids, and in the retort there remains a liquid containing anchoic or lepargylic acid (i. 289), together with small quantities of pimelic and suberic acids.

Cowtree-wax, obtained by evaporation from the milk of the cow-tree (*Palo de Vaca, Brosimum Galactodendron*), is a waxy substance, which softens at 40°, melts at 60°, is insoluble in cold alcohol, but dissolves completely in boiling alcohol, and is saponified by alkalis. According to Berzelius, it resembles beeswax more closely than any other kind of wax. Essentially different from this wax are the resinous bodies and caoutchouc-like substance which Marchand obtained from the milk of the cow-tree. (J. pr. Chem. xxi. 43.)

Cuba-wax is a yellowish-brown wax, of unknown origin, imported from Cuba. It is softer than bees-wax, dissolves in warm ether and turpentine-oil, and almost wholly in boiling alcohol. According to Brandes, it contains 76·5 per cent. cerin, 10·5 myricin, 9·2 balsamic resin, and 3·5 water.

Japan-wax, also called *tree-wax*, and improperly *American wax*, is obtained in the East Indies from the root of *Rhus succedanea*. It is yellowish-white, of about the consistence of bleached beeswax, but somewhat softer and more friable; insoluble in water, slightly soluble in absolute alcohol at ordinary temperatures, completely at the boiling heat, soluble in ether and in volatile and fixed oils. Different samples melt at

42° to 53° or 55°. It is not a true wax, but a glyceride, being resolved by fusion with potassium-hydrate into palmitic acid and glycerin. By dry distillation, it yields palmitic acid and acrolein, a product never obtained from the true waxes. By prolonged boiling with nitric acid, it yields succinic acid.

Stop-wax, or Propolis, is the waxy substance with which bees cover over the cracks in their combs. Boiling alcohol extracts resin from it, leaving a substance called propolin, which melts at 57–58°, emitting an odour of honey. (Pellerin, J. Pharm. viii. 433.)

WAX, FOSSIL. Syn. with OZOCERITE (iv. 322).

WAX-BUTTER.
WAX-OIL. } See WAX (p. 1036).

WEBSTERITE. Native tribasic sulphate of aluminium, $3Al^2O^3.SO^3.9H^2O$, also called aluminite. (See SULPHATES, p. 579.)

WEHRLITE. A massive granular mineral, from Syurraskö in Hungary, resembling lievrite, and containing 34·6 per cent. silica, 0·12 alumina, 42·38 ferric oxide, 15·78 ferrous oxide, 0·28 manganous oxide, 5·84 lime, and 1·00 water, agreeing nearly with the formula $\left.\begin{matrix}\frac{2}{3}FeO\\ \frac{1}{3}CaO\end{matrix}\right\}SiO^2.(Fe^2O^3.SiO^2)$. Before the blowpipe it melts on the edges only; acids decompose it with difficulty. (Wehrle, Leonh. N. Jahrb. 1834, p. 627.)

WEISSIGITE. This name was given by Jenzsch to small felspathic monoclinic crystals, from the almond-stone of Weissig in Saxony, apparently identical with orthoclase (Jahresb. 1853, p. 803; 1854, p. 829; 1855, p. 947).

WEISSITE. A hydrated dichroïte, resembling fahlunite, from Fahlun in Sweden (Trolle-Wachtmeister, Pogg. Ann. xiii. 371; xiv. 190), and Potton in Upper Canada (J. pr. Chem. xiv. 35):

	SiO^2.	Al^2O^3.	FeO.	MnO.	MgO.	CaO.	K^2O.	Na^2O.	H^2O.	
Fahlun	59·69	21·70	1·43	0·63	8·99	0·30	4·10	0·68	3·20	= 100·72
Canada	55·05	22·60	12·60	. .	5·70	1·40	. .	. .	2·25	= 99·60

WELD: *Reseda Luteola.* (*Dyer's Weed. Gaude. Wau.*)—A biennial plant growing wild in many places, especially on chalky soils, and cultivated for use in dyeing. It contains a yellow colouring-matter called luteolin (iii. 736), and is much used for dyeing silk a golden-yellow, and in paper-staining.

WELTER'S BITTER. Syn. with PICRIC ACID (iv. 400).

WERNERITE. Syn. with SCAPOLITE (p. 203).

WHEAT. See CEREALS (i. 823);—also a paper, by Lawes and Gilbert, *On some Points in the Composition of Wheat-grain, its Products in the Mill, and Bread.* (Chem. Soc. Qu. J. x. 1.)

WHEWELLITE. Monoclinic crystals, observed by Brooke on a specimen of calcspar of unknown origin, and consisting, according to Sandall (Phil. Mag. xvi. 449), of calcic oxalate, ($C^2CaO^4.H^2O$?)

WHISKY. Spirit obtained by distilling the fermented wort of corn, sugar, or molasses, but generally the former.

WHITE ANTIMONY. Native antimonious oxide, Sb^2O^3; syn. with VALENTINITE (i. 323).

WHITE ARSENIC. Arsenious oxide, As^2O^3 (i. 373).

WHITE COPPERAS. Native ferric sulphate, $Fe^2(SO^4)^3.9H^2O$, also called Coquimbite (p. 595).

WHITE IRON PYRITES. The trimetric form of native disulphide of iron, FeS^2, also called MARCASITE (iii. 402).

WHITE LEAD. Amorphous basic carbonate of lead, used as a pigment (i. 786).

WHITE-LEAD ORE. Native carbonate of lead, $PbCO^3$.

WHITE PIGMENTS, The white pigment most in use is white lead: it surpasses all others in "body" or opacity, but has the defect of turning black when exposed to an atmosphere containing sulphuretted hydrogen. Sulphate of barium and oxide of zinc are free from this inconvenience; the latter is extensively used as an artist's colour, both for oil- and water-painting. Mixtures of white lead and barium-sulphate are often used in house-painting. Levigated chalk, known in France by the names *blanc d'Espagne, blanc de Meudon, blanc de Bougival, blanc de Troyes ou de Champagne,* according to the locality from which it is obtained, is also employed as a white pigment, but appears to have been used in ancient times much more extensively than at present.

WHITE TELLURIUM. Sylvanite, containing lead and antimony (p. 647).

WHITE VITRIOL. Sulphate of zinc (p. 617).

WHITNEYITE. An arsenide of copper from Houghton County, Michigan; massive, reddish-white; of specific gravity 8·408. Melts easily before the blowpipe, giving off arsenic vapours. Dissolves in nitric acid. Contains, according to Genth (Sill. Am. J. [2], xxvii. 400), 11·61 per cent. arsenic, 88·13 copper, and 0·40 silver and insoluble matter, agreeing with the formula $Cu^{18}As^2$.

WICHTISITE, WIHTISITE, or **WICHTYN.** A silicate from Wihtis in Finland; amorphous; specific gravity = 3·00. Melts before the blowpipe to a black enamel, and is not attacked by acids. Analyses: *a* by Laurent (Ann. Ch. Phys. [2], lix. 109); *b* by Strömborg (Arppe, Analyser af. finska Min. p. 17):

	SiO^2.	Al^2O^3.	Fe^2O^3.	FeO.	MnO.	CaO.	MgO.	Na^2O.		
a.	56·3	13·3	4·0	13·0	. .	6·0	3·0	3·5	=	99·1
b.	54·24	14·27	. .	15·62	2·70	5·65	3·86	3·88	=	100·22

WILLEMITE, WILHELMITE, or **WILLIAMSITE.** Anhydrous orthosilicate of zinc, $\overset{\prime\prime}{Zn}{}^2SiO^4$, or $2ZnO.SiO^2$, occurring in crystals and massive at Franklin, New Jersey, and on the Buchsbach Berg, near Aachen. The crystals are combinations of a rhombohedron with a hexagonal prism. Length of principal axis = 0·685. Angle R : R (terminal) = 115°; oR : R = 141° 39·5′. Cleavage distinct, lateral, and basal. Hardness = 5·5. Specific gravity = 3·935—4·18. Whitish or greenish-yellow, or greyish-white with rather weak vitreo-resinous lustre. Streak uncoloured. Transparent to opaque. Brittle. Fracture conchoïdal. Contains, when pure, 27·54 per cent. silica, and 72·46 zinc-oxide.

A variety called troostite from Sterling, New Jersey, has the zinc partly replaced by iron and manganese, the ferrous and manganous oxide together amounting to about 9 per cent.

WILLIAMSITE. Syn. with WILLEMITE. The name is also applied to a grey, laminar, non-aluminous serpentine, from Westchester, Pennsylvania (p. 237).

WILLOW. The inorganic constituents of the leaves, wood, and bark of *Salix vitellina* have been examined by Reichardt (Arch. Pharm. [2], lxxiii. 257; Jahresb. 1853, pp. 581–585), with especial reference to the variations in their total amount and relative proportions in spring and autumn.

WILSONITE. A silicate from Bathurst in Canada, occurring in monoclinic forms, with rose-red colour; specific gravity = 2·76—2·77; hardness very unequal in different parts. Becomes colourless and gives off water when heated, and melts with intumescence, before the blowpipe, to a white enamel. Contains, according to T. S. Hunt (*Geol. Survey of Canada*, 1853), 43·55 per cent. silica, 27·94 alumina, 0·20 ferric and manganic oxides, 6·50 lime, 3·81 magnesia, 1·45 soda, 8·37 potash, and 8·61 water (= 100·43).

WILUITE. A variety of lime-garnet, also called *grossularia* (see GARNET, ii. 772). The same name is sometimes applied to vesuvian (p. 998).

WIND-FURNACE, or **AIR-FURNACE.** The ordinary furnace used for crucible operations, in which the draught is produced, without the aid of a blast, by the difference of specific gravity of the heated air in the chimney and the external air.

WINE. Synonyms: *Wein. Vin. Vinum.* Οἶνος.—This name is applied, in a general sense, to all alcoholic liquors produced by fermentation of saccharine juices of plants (FERMENTATION, ALCOHOLIC, ii. 628), but it is more usually restricted to the fermented juice of the grapes of *Vitis vinifera.*

The chief constituent of wine, besides water, is alcohol, the amount varying from 6 to 17 per cent. in different kinds of wine, as shown in the following table. The quality and value of wine is, however, determined much less by the amount of alcohol it contains, than by the flavour and bouquet which it possesses. These characters, which are due to the presence, in very minute proportions, of ethereal and aromatic substances, differ in kind in different sorts of wine, and in degree in the same kind of wine. The chemical nature of the substances which constitute the bouquet of different wines is as yet but little known. They are produced, partly during the fermentation of the grape-juice, and chiefly by the mutual reaction of various constituents, when new wine is kept (Berthelot, Compt. rend. lvii. 287, 398, and 795.—Pasteur, *ibid.* p. 936):—

It is stated that in wines imported into England, especially port and sherry, the amount of alcohol is habitually augmented by mixing them with brandy. Natural wine made from grape-juice containing 20 per cent. of glucose should not contain much more than 10 per cent. by weight of alcohol, unless it has been long kept in casks, and there has been a considerable separation of water by evaporation through the wood, and a consequent increase in the amount of alcohol. But if the wine of hot countries is produced from grape-juice containing 30 per cent. of sugar, it might well contain 16 or 17 per cent. of alcohol after being kept in casks.

The peculiar smell which is common to all wine is probably due to the presence of an ether, which Liebig and Pelouze have termed œnanthic ether (iv. 174).

Some kinds of wine, such as Malaga, Tokay, Tent, and Frontignac, contain a considerable amount of sugar; others, like Rhine wine, Bordeaux, and Burgundy, are almost destitute of sugar. The sweetness of wine may, in some cases, be due to the presence of glycerin, which appears to be a product of fermentation (ii. 628).

All kinds of wine contain free acid, which is partly tartaric acid, perhaps also succinic, malic, and citric acids, together with tannic and gallic acids, and acid potassic tartrate.

The colour of wine is chiefly derived from the husks of the grapes, especially in the case of red wine. White wine frequently derives a portion of its colour from the oak-casks in which it is kept. The chemical nature of the substances to which the colour of wine is due is but little known (Fauré, *Analyse chim. et comparée des Vins, &c.*—Batilliat, *Traité sur les Vins de la France.*)

On evaporating wine to dryness at 100° C., it leaves an extract, which varies from 2 to 5 per cent., and sometimes amounts to 10 per cent. and upwards. The amount is less in dry wines than in sweet wine, and it decreases as the wine is kept.

Wine is often liable to undergo certain changes, which render it unfit for use, sometimes becoming turbid or ropy. These effects are chiefly referable to the presence of ferment, or of nitrogenous substance capable of conversion into ferment, and they result from imperfections in the manufacture. Pasteur (Compt. rend. lx. 899, 1109; lxi. 274) recommends heating the wine in closed bottles to about 60° C., for an hour or two, in order to prevent these changes.

Effervescent wines contain carbonic anhydride dissolved under pressure, and resulting from fermentation, produced after bottling the wine by adding to it a solution of sugar.

Manufacture of Wine.—The grapes grown in wine-producing countries generally consist, when ripe, of from 70 to 75 per cent. juice, 20 to 25 per cent. moist skins and stones, and from 3 to 5 per cent. of stalks. The skins are covered with a whitish pulverulent bloom, consisting of a waxy substance. They consist chiefly of compact cellular tissue containing nitrogenous substances, fat, &c., with an internal layer of vegetable tissue containing nitrogenous and colouring-matters, essential oil, tannin, and salts. The fleshy part of the grape consists of cells and vessels, which contain the chief part of the juice. The stones consist chiefly of cellulose, and contain also fatty and ethereal oils, nitrogenous substance, and tannin. The stalks contain acids, tannin, chlorophyll, and similar substances, but scarcely a trace of glucose. The constituents of the juice are chiefly water and glucose, together with gum, pectin, dissolved and suspended nitrogenous substances, tartaric acid—perhaps also racemic acid, malic acid,[*] citric acid,[†] paracitric acid, succinic acid, and acetic acid,[‡] partly free and partly as salts. It also contains fatty and ethereal oils, wax and resin, colour-substance, tannin, phosphates, sulphates, and other mineral substances in small amounts.

The amount of glucose in grape-juice varies from 10 to 30 per cent., according to the climate and season in which the grapes grow; and the amount of free acid, considered as tartaric acid, varies, under the same conditions, from ·3 to 1·5 per cent. The juice of grapes used for making wine is generally colourless, or very slightly yellowish, and it is almost without odour, except that of the Muscat grape. With the exception also of the *teinturier* grape, which has coloured pulp, the yellow and blue colouring substances of grapes are contained in their skins. They are closely analogous to tannin, and are more soluble in alcohol containing acid than in water.

In regard to the production of wine, the principal constituents of grape-juice are glucose, the acids, and the nitrogenous substances which furnish the ferment, so that the raw material for the production of wine may be regarded as a solution of glucose in water, containing also those substances.

It is especially important that the grapes used for making wine should be allowed, as far as possible, to attain full maturity, and become perfectly ripe, in order that there may be a maximum amount of glucose, and a minimum amount of free acid, in the juice (FRUIT, ii. 710, 711). Immediately after the grapes have been gathered, they are crushed, either in vats or between wooden rollers. In some places they are first picked from the stalks, in other places they are pressed together with the stalks. The juice is then either separated at once from the husks and stones, &c., by pressing the crushed grapes, and the expressed juice, or "must," is left in vats to ferment without the "marc"; or the crushed grapes are first allowed to ferment for some time with the husks, as in the manufacture of red wine, and the marc is separated after the fermentation, when sufficient colour has been extracted. During the first stage of the fermentation, the temperature of the liquid rises, and as the conversion of glucose into alcohol progresses, some acid potassic tartrate is deposited (p. 678), together with portions of the ferment and other organic substances, forming what is termed "lees." As the evolution of carbonic anhydride subsides, the liquid gradually becomes clearer. This stage of the fermentation is sometimes at an end within two or three days, but it sometimes lasts much longer. In order to prevent the production of acetic acid by oxidation of alcohol, it is generally customary to draw off the fermented liquor from the lees, as soon as the evolution of gas has become comparatively scanty, and to transfer it to casks in which the fermentation continues slowly, for a considerable time longer, acid potassic tartrate being deposited meanwhile as a crystalline crust on the sides of the casks (TARTAR, p. 671). After a time, when the production of alcohol is at an end, the wine is again transferred to other casks, and is kept for a long time, during which its constituents undergo those changes by which it chiefly acquires flavour, bouquet, and ripeness. In this way what is termed "natural wine" is produced.

---

[*] Pasteur, J. Pharm. [3], xxiv. 75.—Schwartz, Ann. Ch. Pharm. lxxxiv. 83.

[†] Winckler, Jahrb. Pharm. i. 57.

[‡] Berthelot and Fleurieu, Compt. rend. lvii. 397.

During the first stage of the fermentation, which is essentially analogous to that of beer-wort (i. 529), the greater part of the glucose is converted into alcohol, and much of the nitrogenous substance which yields the ferment is separated. The amount of glucose remaining unaltered, depends partly on the amount originally contained in the "must," and partly on the temperature at which the fermentation takes place. At a temperature of 10° C., fermentation ceases when the alcohol produced amounts to 10·5 or 11 per cent. by weight, but at a higher temperature, it may continue until the alcohol amounts to 13 per cent. or more. During the second stage of the fermentation, when the weather has become cooler, there is less fear of alcohol being oxidised, and the moderate access of air to the wine has chiefly the effect of causing the ferment to separate from it.

Hitherto little attention has been paid to the regulation of the temperature at which the fermentation takes place, and although it is highly probable that the quality of wine depends very much upon this circumstance, it is almost entirely a matter of local accident, whether the fermentation takes place at a high or low temperature. Active fermentation at a high temperature, is calculated to furnish wine which is free from sugar, and soon becomes ready for use; but the wine thus produced, like much of the Italian and Hungarian wine, has generally little or no bouquet or flavour, and is not capable of being kept long. On the contrary, slow fermentation at a low temperature, furnishes wine which not only keeps better, but acquires eventually a finer bouquet, and becomes generally of better quality than that produced by more rapid fermentation at a higher temperature. In the Moselle and Rhine districts, the fermentation is conducted at a time of year when the weather is much colder than it is in Italy, and even there, the wine produced in seasons which, from their warmth, are especially favourable to the growth and maturation of the grapes, and continue warm until late in the year, is not always so good as that of years when the autumn is colder.

The character of wine also depends very largely on the composition of the "must" from which it has been produced, especially on the amounts of glucose and of acid which the must contained, and on the relative proportions of these substances. Generally speaking, in southern countries, where the amount of sugar in the grape-juice is largest, as in Greece, Portugal and Spain, the wine produced contains a large amount of alcohol, some unfermented sugar, and but little bouquet as compared with the wine of northern countries, such as that of the Moselle and Rhine districts, which contains less alcohol, no sugar, and a larger amount of acid, but is chiefly characterised by its fine aroma. The grape-juice of these countries generally contains a smaller amount of sugar, and a much larger proportion of acid, than that of southern countries. But besides the differences due to climate, variations of season also exercise a further influence of a similar nature, especially in the northern wine-producing districts, where in cold seasons the amount of sugar is small, while the proportion of acid to sugar in the grape-juice is frequently twice as great as it is in more favourable years, and consequently the wine produced there is only occasionally good, and very often can scarcely be drunk.

To produce good wine, it is essential that the grape-juice should contain at least 20 per cent. of glucose, and that with this amount it should not contain more than ·5 per cent. of acid. These conditions do not always obtain. In the Moselle district, for instance, the proportion of acid to glucose is often as 1 to 12, while the amount of glucose is also very small. In such cases the wine made from natural grape-juice is necessarily inferior; but it is possible to remedy these natural defects of the grape, and by doing so, to render it capable of producing better wine, especially in unfavourable years. With this object, several methods have been proposed, of which the following are among the principal:—

1. Concentrating the grape-juice by partially drying the grapes before they are crushed, or by evaporating the "must."—This method is practised in some parts of Hungary, Spain, Italy, and France, but it has only a limited applicability, and is more adapted to the production of liqueur wines than for improving the quality of wine when the grape contains little sugar and much acid.

2. Adding glucose to the must when it amounts to less than 20 per cent.—This method only partially rectifies the natural defects of the grape-juice, and although it would furnish a wine containing more spirit than that produced from the unmixed must, the excessive amount of acid is not affected except in so far as it may be masked by an excess of sugar.

3. Diluting the must with water sufficient to reduce the amount of acid to ·5 per cent., and then adding glucose until this amounts to 20 per cent. in the must.—The adoption of this method was at first strongly opposed on the ground that wine thus prepared, might be expected to be deficient in flavour and bouquet; but this has been found not to be the case, and the result is quite consistent with the fact that the flavour and bouquet of wine are produced during the fermentation. So far as the product of fermentation is concerned, it is therefore a matter of little consequence whether the glucose has been derived from the grape, or from some other source, provided the grape-juice contains a sufficient amount of ferment, acid, and other substances, requisite for the production of good wine, and these are generally present in excess. The principal condition to be ensured is the purity of the glucose employed.

4. Mixing the pressed grape marc with water containing 20 per cent. of glucose, and fermenting.—This method is based on the important observation, that the marc from which the grape-juice has been expressed, still contains a large amount of those substances, which by fermentation with a solution of glucose, communicate to it the characters of wine, and are capable, under the influence of this process, of yielding the products which constitute the bouquet, etc. (Pétiot, Bulletin soc. d'Encour., 1857, p. 559). The wine prepared by this method, is stated to be even better than that obtained from the grape-juice itself.

These last two methods bear the character of rational improvements in the manufacture of wine, and are in this respect to be regarded as totally different from that system of compounding, justly termed adulteration, which has been practised with the object of giving inferior wine the semblance of character it can acquire only by the process of fermentation, and in the highest degree, only in certain favourable years. Pasteur's method of maturing wine by the application of heat instead of keeping it for a number of years, is likewise an improvement which is sound in principle, and likely to be of considerable advantage. The chemistry of wine is, however, still so imperfectly understood, both as regards its composition and its production, that the methods above referred to must be regarded merely as first steps towards real improvement in the practice of an art which has hitherto been conducted in a most crude and empirical manner, subject to the accidental influence of conditions whose operation and effects were wholly unknown, and regulated by the most fantastic notions.

Analysis of Wine.—The chief data, &c. determined for practical purposes, are:—

1. The amount of *alcohol*; 2. The amount of *free acid*; and 3. The amount of non-volatile dissolved contents, or "*extract*," as it is termed. Neither the flavour nor the bouquet of wine are susceptible of estimation by chemical means. The colouring substances of wine are also too little known to be distinguished with certainty from other colouring substances employed for its adulteration. (Blume, Dingler's Journ. clxx. 240.)

Estimation of Alcohol.—The most trustworthy method consists in distilling out the alcohol as already described under the head of BEER (i. 530), and weighing or observing the density of the distillate (ALCOHOLOMETRY, i. 81). The free acid in the wine should be first neutralised by sodic carbonate or baryta-water, and a very small quantity of tannic acid added to prevent the wine from frothing when distilled. The percentage of absolute alcohol should be expressed by weight, that of proof-spirit by volume.

Estimation of Free Acid.—This may be effected with a standard solution of alkali, as described under ACIDIMETRY (i. 262).

The amount of acid potassic tartrate may be estimated by mixing the wine with five times its volume of mixed alcohol and ether (equal parts) and leaving it for twenty-four hours, when the salt will have deposited almost entirely. (Berthelot and Fleurien, Compt. rend. lvii. 394.)

If it be desirable to ascertain the relative proportions of fixed and volatile acids in wine, this may be done approximately by distilling the wine and estimating the quantity of acid in the distillate; but the result obtained will not represent the full amount of free volatile acid, and cannot be much relied upon.

Estimation of "Extract."—This is made in the same manner as with BEER (i. 530). If the amount is considerable, it may be desirable to ascertain what it consists of.

Estimation of Sugar.—This may be made by one of the methods described under SACCHARIMETRY (p. 371). It is necessary, in using the copper-method, first to separate the colouring substance of the wine. When the fermentation method is adopted, the alcohol in the wine should be first distilled off, and the result obtained by weighing the carbonic acid as barium-carbonate may be checked by estimating the alcohol produced.

The inorganic constituents of wine may be estimated by igniting the residue left on evaporation. The amount of potash thus found may be taken as representing the acid potassic tartrate in the wine.

For more detailed descriptions of the methods and apparatus to be used in the analysis of wine, see Bolley and Paul, *Manual of Technical Analysis*, p. 331, and Griffin, *Chemical Testing of Wines and Spirit;* also a paper by Dr. A. Dupré, *On the Estimation of Compound Ethers in Wine.* (Chem. Soc. J. xx. 493.) B. H. P.

WINE, OIL OF. See ETHERIN (ii. 507).

WISERITE. A hydrated carbonate of manganese, from Gonzen, near Sarganz, in the Grisons; regarded as a variety of diallogite.

WITHAMITE. A bright-red variety of epidote; the crystals exhibit a straw-yellow in one direction across the prism.

WITHERITE. Native carbonate of barium (i. 780).

WITTICHENITE or **WITTICHITE.** Sulphide of copper and bismuth, $Cu^3Bi'''S^3$, from Wittichen in Baden (ii. 76).

WITTINGITE. A ferrico-manganic silicate, from the Wittinge iron-mine at Storkyro in Finland, containing, according to a preliminary analysis by Igelström, 33·28 per cent. silica, 5·93 ferric oxide, 51·79 manganic oxide, and 9·0 water.

WOAD. *Isatis tinctoria.* (*Guède. Pastel. Wau.*)—This plant has been used from ancient times for dyeing blue, and before the introduction of indigo was of great importance for that purpose. Schunck (Phil. Mag. [4], x. 73) has shown that the leaves of woad do not contain either indigo-blue or indigo-white, but indican (iii. 246), a compound which may be extracted from them by alcohol, and is resolved, by heating with dilute acids, into indigo-blue and indiglucin:

$$\underset{\text{Indican.}}{C^{26}H^{31}NO^{17}} + 2H^2O = \underset{\text{Indigo-blue.}}{C^8H^5NO} + \underset{\text{Indiglucin.}}{3C^6H^{10}O^6}.$$

Woad is cultivated in France, in several parts of Germany (Thuringia, Silesia, &c.), and other countries. It is sown in March, and the leaves are cut for the first time in June; later in the season, the plants yield fresh crops of leaves, but these do not contain so much colouring-matter as the first. The leaves are sometimes merely dried, and sent to market in that state; or they are ground to a paste in a mill, and the paste is made up into heaps, left for some time, and then formed into balls or loaves, which are dried and sent into commerce.

At the present day, woad is but rarely employed in dyeing, as the use of indigo is found to be much more economical; but as it easily ferments when moist, it is used for the reduction of indigo in the so-called *woad-vats.* (See INDIGO, ii. 252.)

WÖHLERITE. A silico-zirconio-niobate of calcium and sodium, occurring at the Langesundfjord, near Brevig, in Norway, in tabular crystals and prisms belonging to the trimetric system. Axes $a : b : c = 1 : 1·01583 : 0·7261$. Angle $\infty P : \infty P = 90° 54'$; $oP : \bar{P}\infty = 144° 1'$. Cleavage distinct in one direction. The mineral also occurs granular. Hardness = 5·5. Specific gravity = 3·41. Lustre vitreous, inclining to resinous. Colour light-yellow, brownish, or greyish; streak yellowish-white. Transparent to subtranslucent. Fracture more or less conchoïdal to splintery. When strongly heated before the blowpipe, it melts quietly to a yellowish glass; with fluxes, it gives the reactions of iron, manganese, and silica. Hydrochloric acid decomposes it, with separation of silicic and niobic acids. Contains, according to Scheerer (Pogg. Ann. xcii. 242), 14·47 per cent. Nb^2O^5, 15·17 ZrO^2, 30·62 SiO^2, 1·91 FeO, 1·55 MnO, 26·19 CaO, 0·40 MgO, 8·39 Na^2O, and 0·2 water (= 98·94).

WÖRTHITE. An altered or hydrous kyanite (iii. 449), from near St. Petersburg. Hardness = 7·25, white and translucent. Contains, according to Hess, (Pogg. Ann. xxi. 73), 40·58 per cent. silica, 53·50 Al^2O^3, 1·00 MgO, and 4·63 H^2O (= 99·71).

WOLCHITE. Antimonial copper-glance (ii. 76).

WOLCHONSKOÏTE. A chromiferous clay from Ochansk in Siberia, containing, according to Kersten (Pogg. Ann. xlvii. 485):

SiO^2.	Al^2O^3.	Cr^2O^3.	Fe^2O^3.	CaO.	MgO.	MnO.	H^2O.	
37·01	6·47	17·93	10·43	1·01	1·91	1·66	21·84	= 98·26

WOLFRAM. Native tungstate of manganese and iron (p. 907). The same name is also applied to metallic tungsten.

WOLFRAMINE, or **WOLFRAM-OCHRE.** Native tungstic oxide (p. 903).

WOLFSBERGITE. Native cuprous sulphantimonite, or antimonial copper, $Cu,Sb'''S^2$, or $Cu^2S.Sb^2S^3$ (ii. 76).

WOLLASTONITE. Native metasilicate of calcium, $Ca''SiO^3$ (p. 252).

WONGSHY, or **WONGSKY.** The Chinese name for the pods of *Gardenia grandiflora*, which yield a large quantity of a yellow colouring-matter, 1 pt. of wongshy being sufficient to impart a strong yellow colour to 60 pts. of water. The pods contain also pectin, mucus, tannic acid, and fat. The aqueous extract has a fiery-red colour when concentrated, yellow when dilute. The alcoholic extract is fiery-red.

The colouring-matter of wongshy has been shown by Rochleder to be identical with crocin from saffron (ii. 108).—Respecting the products obtained from it by Orth, see J. pr. Chem. lxv. 16.—Chinese yellow-pods contain 5 per cent. ash, consisting in 100 pts. of 29·2 pts. K^2O, 11·3 Na^2O, 12·0 CaO, 3·5 MgO, 5·5 Fe^2O^3, 0·9 SO^3, 10·3 P^2O^5, 4·0 SiO^2, and 0·5 Cl. (Stein, J. pr. Chem. xlviii. 329.)

The aqueous extract of wongshy colours wool and silk a fine yellow, without mordants; cotton to be dyed with it must first be mordanted, best with tin-solution. The colour withstands the action of soap; alkalis turn it more yellow, acids more reddish. The colour does not withstand the action of light, but is most permanent on silk. The colour of wongshy has a great resemblance to that of annotto.

WOOD. Respecting the chemical composition of wood, two different views are entertained. According to Payen (Compt. rend. viii. 51), v. Baumhauer (J. pr. Chem. xxxii. 204), and F. Schulze (Chem. Centr. 1857, p. 321), it consists of cellulose or woody fibre (i. 818), which forms the cell-walls, and of incrusting substances deposited thereon (*Sclerogen*, *Lignin*, formed of products of decomposition of the decaying cells [Schleiden, *Grundz. d. wiss. Botanik*, Leipzig, 1849, i. 172]). Frémy, on the other hand (Compt. rend. xlviii. 862), denies the existence of incrusting substances, and supposes that the true woody tissue consists of *vasculose*, the constituent of the vessels (p. 995), which is insoluble in oil of vitriol, soluble in boiling concentrated potash-ley; *paracellulose*, the substance of the medullary rays (iv. 34), soluble in oil of vitriol and in boiling potash-ley; and *fibrose*, the substance of the true woody fibres, soluble in oil of vitriol, but insoluble in boiling concentrated potash-ley. The former view is, however, generally regarded as the more exact. Wood likewise contains the following substances, in quantities varying with the season and locality, and with the species and age of the plant: the constituents of the sap, such as albuminoïdal substances (0·81—0·12 per cent. nitrogen, according to Chevandier), sugar, gum, tannic acid, &c., colouring-matters, starch (only in autumn and winter), pectose, according to Frémy (Payen found none), resins and volatile oils, and the ordinary mineral constituents of plants.

The external properties of wood depend, partly on the mode of union of the fibres, partly on the proportions between the essential or adventitious proximate constituents. Hence the several species of wood differ greatly in hardness, colour, and apparent specific gravity. The latter, that is to say, the specific gravity of the wood air-dried, but still *containing air*, varies, according to Karmarsch (*Gründz. d. mech. Technologie*, p. 635), from 0·383 (poplar-wood) to 1·342 (logwood). The actual specific gravity of different kinds of wood is tolerably uniform: 1·5, according to Violette; from 1·46 (maple) to 1·53 (oak), according to Rumford. Wood always contains a larger quantity of carbon than cellulose; its composition varies between very wide limits (according to the nature of the incrusting substances: Payen), as much apparently in the same as in different woods. The lowest and highest amounts actually found are: 46·10 per cent. carbon (beech-wood: Baer), and 54·44 per cent. (oak-wood: Payen); (beech-wood = 54·35);—5·55 per cent. hydrogen (box-wood: Prout), and 6·40 per cent. hydrogen (aspen-wood: Payen);—39·32 per cent. oxygen (oak-wood: Payen), and 46·87 per cent. (beech-wood: Baer).

Decay of Woody Fibre.—Moist wood exposed to the air, gradually undergoes decomposition, a species of fermentation being set up by the nitrogenous constituents, in consequence of which, oxygen is absorbed, carbonic acid and water are evolved, and the wood crumbles down into a blackish-brown vegetable mould, called humus, ulmin, or gein (p. 936). This decay occurs most rapidly in young spongy wood, which admits the air more freely, and at the same time contains a larger proportion of the albuminous substance than harder and older wood.

The process of decay in ligneous tissue varies considerably, according as it takes place with free access of air, or under water with but a scanty supply of oxygen from without. When the air has free access, its oxygen is converted into an equal bulk of carbonic anhydride, and at the same time a large quantity of water is evolved (Saussure). According to Hermann, a small portion of nitrogen is absorbed during the process, and ammonia is produced. The water is formed at the expense of the oxygen and hydrogen of the woody tissue, so that the mouldered products contain a larger proportion of carbon than the wood in its original state. If the moist wood is excluded from the air, a small quantity of carbonic anhydride is evolved during its decay, accompanied, as in the former case, by separation of water; and under certain circumstances, marsh-gas is liberated in considerable quantity.

Such is a general view of the changes which take place in the conversion of woody tissue into humus, peat, lignite, bituminous coal, and anthracite, the proportion of carbon in these successive products of transformation continually increasing, until in the last the carbon is found associated with only small quantities of hydrogen and oxygen. (See Table of the Composition of Wood and Coal, given under COAL, i. 1030, 1031.)

The composition of wood (oak) given in the table may be approximately represented by the empirical formula $C^{34}H^{48}O^{22}$; that of certain kinds of peat by $C^{20}H^{22}O^{8}$; that of Bovey lignite by $C^{27}H^{28}O^{7}$; that of Wigan cannel-coal by $C^{26}H^{20}O^{2}$; and that of Welsh anthracite by $C^{40}H^{16}O$. If now the woody tissue be acted upon by a small quantity of oxygen, such as might be supplied by solution in water, each of these products of transformation may be supposed to be formed by the separation of marsh-gas, carbonic anhydride, and water, in the proportions represented by the following equations:*

$$\begin{array}{llllll}
\underset{\text{Wood.}}{C^{34}H^{48}O^{22}} + O^{3} & = & \underset{\text{Peat.}}{C^{20}H^{22}O^{8}} & + 6CH^{4} & + 8CO^{2} & + H^{2}O \\
\underset{\text{Wood.}}{C^{34}H^{48}O^{22}} + O & = & \underset{\text{Lignite.}}{C^{27}H^{28}O^{7}} & + 2CH^{4} & + 5CO^{2} & + 6H^{2}O \\
\underset{\text{Wood.}}{C^{34}H^{48}O^{22}} + O^{2} & = & \underset{\text{Cannel.}}{C^{26}H^{20}O^{2}} & + 2CH^{4} & + 6CO^{2} & + 10H^{2}O \\
\underset{\text{Wood.}}{2C^{34}H^{48}O^{22}} + O^{5} & = & \underset{\text{Anthracite.}}{C^{40}H^{16}O} & + 12CH^{4} & + 16CO^{2} & + 16H^{2}O.
\end{array}$$

Destructive Distillation of Wood.—The products formed by the distillation of wood in close vessels, vary with the nature of the wood operated on, and the temperature at which the distillation is effected. The decomposition begins at about 140°. The volatile portion of the products includes permanent gases—chiefly carbonic oxide, carbonic anhydride, and hydrogen—together with other bodies, which are liquid or solid at common temperatures, whilst a considerable portion of charcoal remains in the retort. Of the liquid products, one portion is soluble in water, and consists of acetic acid, methylic alcohol, methylic acetate, and acetone, accompanied by water and other bodies but imperfectly known; while the remaining portion is insoluble in water, and constitutes wood-tar, which is a mixture of various liquids holding solid matters in solution or suspension. (See TAR, p. 670.)

The products of the distillation of wood, obtained at the lowest temperature, are those into the composition of which oxygen enters most abundantly—such as water, acetic acid, and carbonic acid. As the temperature rises, compounds containing less oxygen are gradually formed—such as wood-spirit, acetone, and creosote; at a still higher temperature, various hydrocarbons, such as toluene, xylene, eupione, and the different forms of paraffin, are produced; and as the temperature approaches redness, pure hydrogen predominates.

When air-dried hard woods, such as oak and beech, are distilled in iron cylinders, the charcoal amounts to about 25 per cent. of the weight of the wood, or about three-fifths of the quantity of carbon actually contained in it. The liquid portion, amounting to about 53 per cent., contains about one-fifth of the entire carbon in the wood; and the remaining portion of the distillate, consisting of uncondensed gas, carries off the remainder of the carbon. Among the liquid products, acetic acid amounts to between 3 and 4 per cent. of the harder woods, naphtha to about 1 per cent., and the tar to 7·5 per cent. (Miller's *Elements of Chemistry*, 3rd ed., iii. 702; for further details see Gmelin's *Handbook*, xv. 148–160.)

WOOD-OIL. *Capivi-balsam, Gurjun-balsam, Gwegun-balsam.* (Hanbury, Pharm. J. Trans. January, 1856, p. 321.—Martius, Buchn. N. Repert. v. 100.—Guibourt, *ibid.* vi. 97.—Werner, Zeitschr. f. Chem. 1862, p. 588.—A balsamic substance, much resembling balsam of copaiba (i. 492), imported of late years from Calcutta into this country for medicinal uses. It is obtained from several species of

a shining, tumefied, difficultly combustible cinder, whic
when completely burnt; the smoke smells like burnt h

Vegetable fibres, on the other hand, leave a cinder having the form of the thread, and only a small quantity of ash; they burn with a smoke which has an empyreumatic odour, and reddens litmus. Wool and silk are also distinguished from cotton and linen by the yellow colour which they assume when steeped in *nitric* or in *picric acid*, the vegetable fibres not being coloured by this treatment. Wool or silk is dissolved by boiling with *potash-* or *soda-ley*, of specific gravity 1·04 to 1·05, whereas vegetable fibres remain unattacked. Cotton and linen dissolve in a solution of *cuprate of ammonium*, whereas wool is insoluble therein.

Wool and silk may be distinguished from one another by a solution of *sodic plumbate* (prepared by adding caustic soda to acetate of lead till the resulting precipitate redissolves), wool and hair being turned brown by this liquid, in consequence of the sulphur which they contain, whereas silk, which is free from sulphur, remains unaltered. The three following distinctions are given by Grothe (Zeitschr. anal. Chem. iii. 153): —1. Wool, cautiously heated to 130°, gives off the odour of carbonic disulphide and ammonia, assumes a golden-yellow colour, and curls up; silk becomes coloured only at 140°–145°, and does not curl up.—2. When the fibres, moistened with potash-ley, are dipped in a solution of *cupric sulphate*, and then exposed to the air, the wool quickly turns brown, in consequence of the formation of cupric sulphide, whereas the silk remains unchanged.—3. On mixing the solution of wool in caustic potash with *tartaric acid*, and then with *cupric sulphate*, a large quantity of cupric sulphide is formed, and the filtered liquid exhibits a dark brown-red colour. Silk treated in the same manner, yields a somewhat viscid solution having a fine violet colour.

WOORARA. Syn. with CURARA (ii. 185).

WOOTZ. *East Indian*, or *Persian Damask Steel.*—A very hard steel, made in India, and containing small quantities of silicon, manganese, nickel, and tungsten. It has a specific gravity of 7·727 at 17°, and exhibits very beautiful patterns when etched with acids.

WORMSEED. *Semen Cinæ. Semen Contra. Semen Santonici.*—The flower-buds of *Artemisia Vahliana, A. Sieberi*, and *A. inculta*, plants belonging to the composite order. The first is indigenous in Persia and Asia Minor, and yields Levant wormseed; the second grows in Barbary, Persia, and Arabia, and yields the Barbary or African wormseed; the third is said to yield the East Indian wormseed, which however, according to some authorities, is merely the African variety mixed with turmeric or fustic.

Wormseed contains santonin (p. 189), a volatile oil, a brown bitter resin, a green soft resin, and a waxy substance, together with the ordinary plant-constituents. It is used, especially the Levant variety, as a remedy for ascarides, being given either as an electuary or an infusion. It is not known which of the constituents of wormseed is the active principle.

WORMSEED-OIL. *Oleum cinæ. Essence de Semen-contra.* (Trommsdorff, Tr. N. J. iii. 312.—Völckel, Ann. Ch. Pharm. xxxviii. 110; lxxxvii. 312; Jahresb. 1853, p. 512; 1854, p. 590.—Hirzel, Jahresb. 1854, p. 591; 1855, p. 655.—Kraut and Wahlforss (Ann. Ch. Pharm. cxxviii. 293; Jahresb. 1863, p. 551.—Gm., xiv. 316.)—This oil is obtained by distilling wormseed with water. It has a pale-yellow to brownish-yellow colour, a pungent disagreeable odour, and camphorous, aromatic, burning taste; specific gravity = 0·925 to 0·935 (Wackenroder; Zeller; Völckel); 0·94 (Hirzel). It boils at 170°—180° (Hirzel). When distilled with milk of lime, it yields a lighter oil, of specific gravity 0·945° at 8°, and boiling between 174° and at 177°.

Wormseed-oil is a mixture of several oils, the proportions of which seem to vary considerably in different samples: hence the investigations of different chemists respecting it have yielded very discordant results. According to Kraut and Wahlforss, the oil, when purified by rectification with alcoholic potash, consists mainly of an oxygenated oil, $C^{10}H^{18}O$, having a lævorotatory power of 2·1°, mixed with a camphene, $C^{10}H^{16}$ (Völckel's cynene).

Wormseed-oil dissolves in about 1000 pts. of water, easily in ether, in all proportions of absolute alcohol, and in an equal quantity of alcohol of specific gravity 1·85 (Zeller). In contact with the air, it thickens and becomes coloured; it is easily inflammable.—With dilute *nitric acid*, it yields oxalic acid (Völckel), or toluic acid (Hirzel); when heated with strong nitric acid, it is converted into a yellow resin.

Iodine dissolves in wormseed-oil without evolution of heat. By dissolving 1 pt. of iodine in 4 to 6 pts. of the oil, with aid of heat, a dark brown-red, opaque, viscid mass is obtained, from which, on cooling, black crystalline laminæ separate (consisting of iodine and cinæbene?). From the solution of iodine in wormseed-oil, water extracts acetic, propionic, and hydriodic acids, and perhaps also iodide of propyl. On distilling the solution of iodine in wormseed-oil, propionic acid and iodoform pass over, together with a dark-brown mobile oil, containing cinæbene, hydriodate of cinæbene, cinæbene-camphor, cymene, and small quantities of cinacrol, angelic acid, &c., while the solid blue-black residue consists chiefly of cinæphene, cinæphane, and cinæphone (Hirzel). Wormseed-oil, mixed with a saturated solution of iodine in potassium-iodide, yields greenish metallic-shining crystals of the compound $2(C^{10}H^{18}O.H^{2}O).I^{2}$, which, when treated with alcoholic potash, reproduces wormseed-oil. (Kraut and Wahlforss.)

Sulphuric acid colours wormseed-oil red-brown, and on applying heat, sulphurous anhydride is evolved.—*Phosphoric anhydride* blackens it, and, according to Völckel, forms cynene; according to Hirzel, cinæbene, cinæphene, and cinacrol.—*Hydrochloric acid gas* is absorbed by wormseed-oil, forming a red-brown liquid, which on standing, deposits **wormseed-camphor**, in colourless slender needles having an aromatic camphor-like odour and mild warm taste; they deliquesce in the air, melt when heated, and yield, by distillation, an oil containing hydrochloric acid. (Hirzel and Völckel.)

Wormseed-oil distilled with *potassium-hydrate* yields a colourless, transparent, mobile oil, having a peppery odour and warm taste, a specific gravity of 0·932, and boiling at about 175°. With hydrochloric acid gas, this oil forms shining deliquescent needles; with nitric acid, liquid and resinous products; sulphuric acid colours it dark-brown, and renders it viscid. This oil has a composition represented by the empirical formula $C^{24}H^{40}O^{2}$, and consists, according to Hirzel, of cinæbene, cinæbene-camphor, propione, and a body containing $C^{10}H^{16}O$.

Derivatives of Wormseed-oil.

Cinæbene, $C^{10}H^{16}$ (with which Völckel's cynene is probably identical), exists ready-formed in wormseed-oil, and is separated by distilling the oil with phosphoric anhydride (Hirzel). It is a colourless, mobile, pungent, strongly-refracting oil, having a density of 0·878 at 16°, and boiling at 172°. When distilled with an equal volume of nitric acid of specific gravity 1·16, it yields acetic acid, propionic acid, and volatile oil, and leaves a resin, which, by prolonged boiling with excess of nitric acid, is converted into toluic and nitrotoluic acids, together with an oil, probably anisylous acid; no oxalic acid is formed in this reaction.—With *hydriodic acid*, cinæbene forms an oily hydriodate, $2C^{10}H^{16}.HI$.

Cinæbene-camphor, $C^{10}H^{18}O$, is contained, according to Hirzel, in wormseed-oil, but cannot be separated from it in the pure state. With phosphoric anhydride it is resolved into water and cinæbene. According to Kraut and Wahlforss, wormseed-oil, purified by alcoholic potash, consists of an oil, $C^{10}H^{18}O$, mixed with the camphene, $C^{10}H^{16}$, which cannot be separated by fractional distillation.

Cinæphene, $C^{20}H^{32}$, is one of the compounds formed by the action of phosphoric anhydride or iodine on wormseed-oil. It is an oil, viscid at ordinary temperatures, mobile when warm, boiling at 315°—325°, colourless by transmitted light, and exhibiting a deep indigo-blue iridescence by reflected light. When heated with nitric acid, it is converted into a resin having a musk-like odour. (Hirzel.)

Cinæphane, $C^{10}H^{8}$, is a resinous hydrocarbon found in the residue left on distilling wormseed-oil with iodine. To separate it, this residue is boiled with alcohol, which dissolves cinæphene; the remaining portion is dissolved in chloroform; the solution is mixed with 20 pts. of alcohol of specific gravity 0·84; and the resulting precipitate of cinæphane and cinæphone is treated with ether, which dissolves the latter, and leaves the cinæphane, to be further purified by solution in chloroform, precipitation with alcohol, and washing with ether. Cinæphane is a nearly velvet-black, loose, resinous powder, tasteless and inodorous; when heated it burns away without melting.

Cinæphone, $C^{10}H^{12}$, separated from cinæphene by ether in the manner just described, is a loosely coherent kermes-brown powder, destitute of taste and odour, insoluble in water and in alcohol, but soluble in ether, chloroform, and wormseed-oil; when heated, it burns and decomposes. (Hirzel.)

Cinacrol, $C^{10}H^{18}O^{2}$, is obtained by rectifying the oil produced by distilling 1 pt. of iodine with 4 to 6 pts. of wormseed-oil; agitating the nearly black liquid which passes over with strong potash-ley; heating the resulting dark-brown solution till it is nearly inodorous; and then distilling it with dilute sulphuric acid. The oil thus obtained is, after drying and rectification, colourless and viscid, with a faint smoky odour, and sharp caustic taste; a specific gravity of 1·05 to 1·15; boils at about 250°; dissolves slightly in water, easily in alcohol, ether, and acetic acid; still more easily in alkalis, forming a solution which gives a white precipitate with basic acetate of lead, a blue-green liquid with ferric chloride, and reduces nitrate of silver when heated with it. (Hirzel.)

WOULFE'S APPARATUS. An apparatus consisting of a series of three-necked bottles connected by suitable tubes, and used for washing gases or saturating liquids therewith.

WRIGHTINE. A basic substance obtained from the bark and seeds of *Wrightia antidysenterica* (*Nerium antidysentericum*, L.), an apocynaceous plant indigenous in India and Ceylon. To prepare it, the pulverised seeds are treated with carbonic disulphide in a displacement-apparatus, to remove a fat-oil, then dried and exhausted with hot alcohol; the extract, freed from alcohol by distillation, is digested with a small quantity of dilute hydrochloric acid; and the evaporated filtrate is mixed with ammonia or sodic carbonate, which throws down a copious flocculent precipitate consisting of the impure base.

Wrightine, after washing with cold water, forms an amorphous powder, insoluble in ether and in carbonic disulphide, soluble in water and alcohol, and especially in dilute acids, with which it forms uncrystallisable salts, having, like the base itself, a persistent bitter taste. The acetic acid solution is precipitated by tannic acid: the hydrochloric acid solution gives flocculent precipitates with platinic, auric, and mercuric chlorides. (Stenhouse, Pharm. J. Trans. [2], v. 493.)

R. Haines (*ibid.* vi. 432) states that he obtained the same base from the bark of *Wrightia dysenterica* (conessi-bark) in 1858, and gave a short description of it in the *Transactions of the Medical and Physical Society of Bombay* (new series, iv. 38). He proposes to call it conessine, and calculates, from the analysis of the free base and of the platinum-salt, the formulæ $C^{26}H^{42}N^2O$ and $C^{25}H^{44}N^2O$.

WULFENITE. Native molybdate of lead. (See Molybdenum, iii. 1039.)

WURTZITE. This name is given by Friedel (Compt. rend. lii. 983) to a hexagonal zinc-sulphide from the silver-mine of Oruro in Bolivia, containing 55·6 per cent. zinc, 32·6 sulphur, 8·0 iron, and 2·7 lead, with a little antimony and a trace of copper. It is isomorphous with greenockite, has a brownish-black colour, vitreous lustre, brown streak; hardness = 3·5, and specific gravity = 3·98.

X

XANTHAMIDE. Syn. with ethylic oxysulphocarbamate. (See Sulphocarbamic Ethers, p. 491.)

XANTHAMYLAMIDE. Amylic oxysulphocarbamate (p. 493).

XANTHAMYLIC ACID. Syn. with amyl-disulphocarbonic acid. (See Sulphocarbonic Ethers, p. 496.)

XANTHAMYLIC ETHER. Amylic disulphocarbonate (p. 496).

XANTHAN. Berzelius's name for the group Cy^2S^3, regarded as the radicle of persulphocyanic or xanthydric acid.

XANTHARIN, or **XANTHIL.** An oily fetid compound, $C^4H^{10}O^3$, supposed by Couerbe (Ann. Ch. Phys. [2], lxi. 225) to be produced by the dry distillation of xanthic ether.

XANTHAZARIN. A yellow colouring-matter, produced, according to E. Kopp (Jahresb. 1864, p. 815), by the action of nitric acid on the black residue obtained in preparing pure alizarin from his green alizarin (see Madder, iii. 749). It is slightly soluble in water, easily in alcohol, ether, and caustic alkalis. By heating with reducing agents, it is converted into a crimson substance.

XANTHEÏN. The name applied by Frémy and Cloez to that portion of the yellow colouring-matter of flowers which is soluble in water. (See Flowers, Colours of, ii. 668.)

XANTHELENE. Zeise gave this name to an oil (identical, according to Debus, with ethyl-disulphocarbonic sulphide, i. 499), produced, together with cuprous xanthate, by precipitating potassic ethylsulphocarbonate with a cupric salt. (Handw. d. Chem. 2te Aufl. i. 250.)

XANTHENE. Völckel, by heating persulphocyanic acid to about 150°, obtained a peculiar body, $C^3H^4N^4S^2$, which he regarded as a sulphide of xanthene, $C^3H^4N^4$; it was probably only a mixture.

XANTHIC ACID. Syn. with ethyl-disulphocarbonic acid. (See Sulphocarbonic Ethers, p. 498.)

XANTHIC ETHERS. Ethylic xanthate or disulphocarbonate (p. 500).

XANTHIC OXIDE. Syn. with XANTHINE.

XANTHIDES. Syn. with PERSULPHOCYANATES (iv. 379).

XANTHIL. Syn. with XANTHARIN.

XANTHIN. This name has been applied to more than one substance:—1. By Frémy and Cloez, to that portion of the yellow colouring-matter of flowers, which is insoluble in water (ii. 668);—2. By Schunck and Higgin, to the yellow colouring-matter obtained by Kuhlmann from madder (iii. 743);—3. By Couerbe, to a gaseous product of the decomposition of xanthates, to which he assigned the formula $C^2H^2S^2O^2$.

XANTHINE. $C^5H^4N^4O^2$. *Xanthic Oxide.* (Marcet, *Essay on the Chemical History and Chemical Treatment of Calculous Disorders*, London, 1819.—Liebig and Wöhler, Ann. Ch. Pharm. xxvi. 340.—Göbel, Jahresb. 1851, p. 604; 1852, p. 712.—Scherer, Ann. Ch. Pharm. cvii. 314; cxii. 257, 275, 279; Jahresb. 1858, p. 546; 1859, p. 605.—Strecker, Ann. Ch. Pharm. cviii. 141; cxviii. 151; Jahresb. 1858, p. 546; 1861, p. 526.—Städeler, Ann. Ch. Pharm. cxi. 28; cxv. 102; Jahresb. 1859, p. 603; 1860, p. 579.—Bence-Jones, Chem. Soc. Qu. J. xv. 78.—Almén, Jahresb. 1862, p. 534.—Strecker and Rheineck, Ann. Ch. Pharm. cxxxi. 121.)—This body was discovered by Marcet in a urinary calculus weighing only 8 grains. Liebig and Wöhler afterwards found it in a larger calculus weighing between 18 and 20 grammes; these are the only known examples of xanthine calculi. Bence-Jones found in it a deposit from the urine of a boy. According to Scherer, xanthine is a normal constituent of the human body; he has found it in the urine of man, in the pancreas, spleen, and liver of oxen, in the thymous gland of the calf, the muscular flesh of the ox, horse, and of fishes; also in the spleen, in a case of tumour of that organ; and in the human liver, in acute yellow atrophy. In the muscular flesh of the horse it exists to the amount of 0·0026 per cent., together with hypoxanthine or sarcine; in the pancreas to the amount of 0·0166 per cent., together with guanine; in the spleen, liver, and brain, together with uric acid. Almén found 0·02 per cent. xanthine in ox-liver. According to E. Dürr (Jahresb. 1865, p. 675), the presence of xanthine in human urine is promoted by the use of sulphur-baths. According to Unger and Phipson (Chem. News [1862], vi. 16), xanthine is found in certain kinds of guano from the island of Jarvis.

Artificial Formation.—Xanthine is produced:—1. From uric acid, from which it differs by 1 at. O, by the action of sodium-amalgam (Rheineck).—2. From guanine, from which it differs by NH, by the action of nitrous acid (Strecker):

$$2C^5H^5N^5O + O^2 = 2C^5H^4N^4O^2 + H^2O + N^2.$$

Preparation.—1. From *Urinary Calculi*, and from *Jarvis Guano*.—By dissolving the substance in aqueous potash or ammonia, and precipitating with carbonic or acetic acid.

2. From *Muscular Flesh* and other *Animal Substances*.—The substance, comminuted by trituration with pounded glass, is digested with warm alcohol and pressed; the residue is digested for some hours with water at 50°; the expressed liquid is mixed with the alcoholic solution, evaporated, and filtered to separate albumin; and the filtrate is successively precipitated with neutral lead-acetate, basic lead-acetate, and mercuric acetate. The two latter precipitates are then suspended in water, and decomposed by sulphydric acid; and the filtered liquid is evaporated, whereby a mixture of xanthine and sarcine is obtained, which may be separated by solution in hydrochloric acid—hydrochlorate of xanthine then separating out, while the greater part of the sarcine remains in solution. (Städeler.)

3. From *Guanine*.—The solution of guanine in strong nitric acid is mixed, at the boiling heat, with nitrite of potassium, till a copious evolution of red fumes takes place. A large quantity of water is then added; the yellow body thereby precipitated (a mixture of xanthine and nitroxanthine) is washed with water and dissolved in boiling carbonate of ammonia; and the solution is mixed with ferrous sulphate (to reduce the nitroxanthine to xanthine), till the red-brown precipitate of ferric hydrate at first produced is replaced by black ferroso-ferric oxide. The solution, which should still contain a large quantity of free ammonia, is then filtered, and evaporated to dryness over the water-bath; the residue is treated with cold water to extract sulphate of ammonium, then redissolved in boiling carbonate of ammonium; and the filtrate is evaporated, whereupon xanthine remains.

4. From *Urine*.—The urine is precipitated with baryta-water; the filtrate is evaporated; the highly concentrated mother-liquor boiled, after addition of water, with cupric acetate; the precipitate, after washing with hot water, is dissolved in warm

nitric acid, and precipitated with nitrate of silver; the washed precipitate is crystallised from hot dilute nitric acid; the resulting crystals are treated with ammoniacal silver-solution, to free them from nitric acid; and the washed precipitate is suspended in water, and decomposed by sulphydric acid. The filtrate, when evaporated, yields xanthine.

Properties.—Xanthine separates on cooling, from a hot saturated solution, in white flocks; by spontaneous evaporation in small scales. It is nearly insoluble in cold water (requiring 14,000 pts.), and but sparingly soluble in boiling water. It is insoluble in alcohol and in ether. The aqueous solution quickly putrefies.

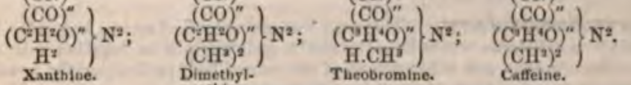
Xanthine does not lose weight at 150°; at a stronger heat, a small portion of it sublimes undecomposed, while the greater part decomposes, yielding carbonate and cyanide of ammonium, and a yellow oil, but no urea. When heated in contact with the air, it burns with the smell of burnt hair.—By the action of sodium-amalgam containing a very small proportion of sodium, xanthine is reduced to sarcine, $C^5H^4N^4O$, this base being in fact produced, together with xanthine, by the action of sodium-amalgam on uric acid (p. 1050).

Combinations.—Xanthine unites both with acids and with bases, forming for the most part crystallisable compounds, which are more soluble than xanthine itself.—The *hydrochlorate*, $C^5H^4N^4O^2.HCl$, forms nodular groups of small silky crystals. Its aqueous solution mixed with *platinic chloride* deposits yellow needles of a double salt.—The *nitrate* separates from a solution of xanthine in warm moderately strong nitric acid, in yellow warty masses. The solution of xanthine in nitric acid forms, with *phosphomolybdic acid*, a yellow precipitate, which dissolves in hot moderately strong nitric acid, and separates, on cooling, in yellow microscopic cubes (Scherer).—The *sulphate*, $C^5H^4N^4O^2.H^2SO^4 + H^2O$, forms thin, transparent, crystalline scales, which are decomposed by water.

A solution of xanthine in *ammonia*, saturated at the boiling heat, deposits, on cooling, crystals of xanthine-ammonia. On boiling xanthine with *baryta-water*, a sparingly soluble compound, $C^5H^4N^4O^2.Ba''H^2O^2$, is produced. (Strecker.)

A cold saturated aqueous solution of xanthine gives white precipitates with mercuric chloride and silver nitrate, yellowish-green flocks with cupric acetate. The ammoniacal solution of xanthine gives white precipitates with the chlorides of mercury, zinc, and cadmium; with nitrate of silver, it forms yellowish-white flocks of the compound $C^5H^4N^4O^2.Ag^2O$, which turn black on boiling.—From a solution of xanthine in nitric acid, silver-nitrate throws down flocks, probably consisting of a compound of xanthine with silver-nitrate, which, if left in the hot liquid, gradually become crystalline; water abstracts nitric acid from them.

The silver-compound of xanthine, heated with methylic iodide, yields **dimethylxanthine**, $C^5H^2(CH^3)^2N^4O^2$, isomeric but not identical with theobromine. Strecker represents the relation between these three bases and caffeine by the following rational formulæ:



$$\left.\begin{array}{c}(CN)^2\\(CO)''\\(C^2H^2O)''\\H^2\end{array}\right\}N^2;\quad \left.\begin{array}{c}(CN)^2\\(CO)''\\(C^2H^2O)''\\(CH^3)^2\end{array}\right\}N^2;\quad \left.\begin{array}{c}(CN)^2\\(CO)''\\(C^3H^4O)''\\H.CH^3\end{array}\right\}N^2;\quad \left.\begin{array}{c}(CN)^2\\(CO)''\\(C^3H^4O)''\\(CH^3)^2\end{array}\right\}N^2.$$

Xanthine. Dimethyl-xanthine. Theobromine. Caffeine.

XANTHININE. $C^4H^3N^3O^2$. (C. Finck, Ann. Ch. Pharm. cxxxii. 298; Jahresb. 1864, p. 642.)—A base produced, together with sulphate of ammonium, by heating thionurate of ammonium to 200°:

$$C^4H^3(NH^4)^2N^3SO^6 \;=\; (NH^4)^2SO^4 \;+\; C^4H^3N^3O^2.$$

On boiling the resulting mass with water, the xanthinine remains as a yellow powder, which may be purified by solution in alkalis, precipitation with acids, and treatment with strong nitric acid. It dissolves in about 4,000 pts. of boiling and 40,000 pts. of cold water, to a light-blue fluorescent solution, which is precipitated white by mercuric chloride, yellow by silver-nitrate. It dissolves in strong nitric and hydrochloric acids, somewhat more freely than in water, and separates therefrom in crystalline laminæ. The solution in concentrated sulphuric acid, decolorised with a little nitric acid, deposits sulphate of xanthinine in laminar crystals, which are decomposed by water, with separation of white pulverulent xanthinine. On dropping an ammoniacal solution of xanthinine into an excess of silver-nitrate, a bulky yellow silver-compound, $C^4H^3N^3O^2.Ag^2O$, is formed, insoluble in water and in ammonia.

XANTHINOCARPIN. A yellow colouring-matter, contained, according to Cuzent (Jahresb. 1859, p. 564), in the juice which exudes from incisions in the bark or fruit of *Inocarpus edulis*.

XANTHIN-SPAR. Syn. with Wulfenite (p. 1049).

XANTHITANE. A mineral from Green River, in Henderson County, North Carolina, probably a pseudomorph after titanite. It is earthy, yellowish-white, with faint lustre; brittle; hardness = 3·5; specific gravity = 2·7 to 3·0. Gives off water when heated in a tube, and exhibits with fluxes the reactions of titanium. (Shepard, J. pr. Chem. Bd. lxix.)

XANTHITE. A variety of vesuvian occuring at Amity, in the State of New York, in indistinct, four-sided, prismatic crystals and crystalline granules, imbedded in limestone. (Dana, ii. 199.)

XANTHOBETIC ACID. An acid contained, according to L. Meier, in the root of *Beta vulgaris*. It is obtained by precipitating the cold aqueous extract with neutral acetate of lead, boiling the precipitate repeatedly with water, then drenching it with alcohol of 80 per cent., and evaporating the extract to dryness after addition of dilute sulphuric acid. On exhausting the brown residue with cold alcohol, and evaporating, xanthobetic acid remains as a reddish-yellow mass, having a sour taste, very hygroscopic, slightly soluble in ether, easily in alcohol and in water. Alkalis and alkaline earths colour it red, and form soluble crystalline salts, from which the xanthobetic acid is separated by stronger acids in its original state. The xanthobetates of the heavy metals are insoluble, and are obtained by precipitation. (Handw. d. Chem. ix. 828.)

XANTHOCHYMUS. The juice of *Xanthochymus pictorius* (formerly supposed to contain gamboge) is greyish-green, and contains 65·5 per cent. resin, 17·6 gum, and 5·9 woody fibre; no volatile oil. (Christison, Ann. Ch. Pharm. lxxvi. 347.)

XANTHOCOBALTIC SALTS. See Cobalt-bases, Ammoniacal (i. 1054); for the view of their composition proposed by C. D. Braun, see Jahresb. 1862, p. 210; 1864, p. 270.

XANTHOCONE. $Ag^3AsS^4.2Ag^3AsS^3$.—A silver-ore from the Himmelfürst mine, near Freiberg in Saxony, crystallising, according to A. Breithaupt (Pogg. Ann. lxiv. 272), in rhombohedral plates, having a brown to orange-yellow colour and adamantine lustre; transparent to translucent, somewhat brittle; hardness = 2·3; specific gravity = 5·0 to 5·2.

XANTHOCYSTIN. See Tyrosine (p. 931).

XANTHOGEN. A name applied by Hope (J. pr. Chem. x. 269) to a substance (called "resin of flowers" by Clamor-Marquart), which he supposed to be very widely diffused in the vegetable kingdom, and to be turned yellow by alkalis. (See Flowers, Colours of, ii. 668.)

XANTHOGEN-OIL. Zeise's name for an oily product formed by the dry distillation of potassic xanthate (p. 498).

XANTHOGLOBULIN. This name was given by Scherer (Ann. Ch. Pharm. cxii. 257) to a substance which he obtained in yellow globules, together with sarcine, from the liver, spleen, and other organs of the animal body; subsequently, however, he found that it was a mixture of xanthine and sarcine.

XANTHOLCIN. A yellow colouring-matter from the seed-capsules of *Sorghum saccharatum*.

XANTHOLEIN. A yellow colouring-matter obtained from the bark of *Sorghum saccharatum*. (Secard, Itier, and Joulie, Compt. rend. xliv. 19, 141.)

XANTHOMETHYLIC ACID. See Sulphocarbonic Ethers (p. 501).

XANTHOPENIC ACID. A product of the decomposition of opiammone by aqueous alkalis (iv. 207).

XANTHOPHENIC ACID. A yellow colouring-matter, of unknown composition, produced, according to Fol (Rép. Chim. App. 1862, p. 179; Jahresb. 1862, p. 697), by heating phenol or cresol with arsenic acid. It dissolves in water with golden-yellow colour, in aqueous alkalis with red colour, and forms reddish salts. The free acid dyes silk and wool yellow, without the aid of mordants, and the dyed stuffs may be treated with soap. The xanthophenates dye silk and wool red, of various shades, from the darkest red to the lightest rose-colour.

XANTHOPHYLL. The yellow colouring-matter of withered leaves. Nothing certain is known respecting its composition, or of the manner in which it is formed from chlorophyll. (See Handw. d. Chem. 2^{te} Aufl. ii. [2], 10, art. Blattgrün.)

XANTHOPHYLLITE. See CLINTONITE (i. 1026).

XANTHOPICRIN. XANTHOPICRITE. These names were given, by Chevallier and Pelletan (Ann. Ch. Phys. [2], xxxiv. 200), to a yellow colouring-matter from the bark of *Xanthoxylon caribæum*, since shown by Perrins (Pharm. J. Trans. [2], iv. 465), to be identical with berberine (i. 579).

XANTHOPROTEIC ACID. An acid formed by the action of nitric acid on albumin, fibrin, casein, and horny matters. It is purified by boiling water and alcohol (Mülder, J. pr. Chem. xvi. 397; xx. 352). It is an orange-yellow, amorphous, inodorous, and tasteless substance, which reddens vegetable colours. It is charred by heat without melting, diffusing an odour of burnt horn; forms deep red solutions with alkalis, and is precipitated therefrom by acids. Dissolves in concentrated acids, and is precipitated by water from the acid solutions in combination with the acid employed. These precipitates are decomposed by washing:—

	Mülder.	Van der Pant. (Average of 11 analyses.)
Carbon . . .	50·78	50·0
Hydrogen . . .	6·60	6·3
Nitrogen . . .	14·00	14·7
Sulphur . . .	"	1·3
Oxygen . . .	"	"

Mülder considers xanthoproteic acid to be dibasic, and ascribes to it the formula $C^{34}H^{26}N^{4}O^{14}$. Xanthoproteic acid is decomposed by boiling concentrated *potash*, yielding ammonia. When *chlorine* is passed through an ammoniacal solution of the acid, the liquid is decolorised, and a yellow precipitate, containing chlorine, is formed.

The *potassium-* and *sodium-salts* do not crystallise; they have a fine red colour.—The *ammonium-salt* is red, and parts with all its ammonia at 140°.—The *barium-* and *calcium-salts* are red, very soluble in water, and insoluble in alcohol and in ether.—The *barium-salt* contains 12·9 per cent. BaO (Van der Pant).—The *iron-* and *copper-salts* are orange, and become red on drying.—The *lead-salt* forms a yellow precipitate becoming red by desiccation, and contains 14 per cent. PbO.—The *silver-salt* resembles the preceding.

Neither the acid nor its salts explode by heat.

XANTHOPYRITE. Syn. with IRON PYRITES (iii. 403).

XANTHORHAMNIN. A yellow colouring-matter obtained from Persian or Turkey berries, the seeds of *Rhamnus amygdalinus*, *R. oleoïdes*, *R. saxatilis*, and from Avignon grains, the seeds of *R. infectorius* (p. 100). According to Kane (Phil. Mag. [3], xxiii. 3), it has the composition $C^{23}H^{24}O^{14}$, and occurs only in the ripe seeds, being formed by decomposition of the chrysorhamnin contained in the unripe seeds (i. 960). It is also produced by boiling chrysorhamnin with water, in contact with the air; and when unripe Persian berries are boiled with water for some time, and dried, they are afterwards found to contain, not chrysorhamnin, but xanthorhamnin. Xanthorhamnin dried in a vacuum over oil of vitriol, is deliquescent, melts below 100°, and continues to give off water till heated to 200°, and then solidifies to a brittle mass. It decomposes above 200°, dissolves easily in water and in alcohol, but is quite insoluble in ether. The aqueous solution is precipitated by neutral and basic acetate of lead. (Kane.)

According to Gellatly (N. Edinb. Phil. J. vii. 252), xanthorhamnin has the composition $C^{23}H^{28}O^{14}$, and exists ready-formed in the unripe berries. To obtain it, the coarsely-ground berries are boiled with alcohol; the tincture, not too concentrated, is freed by standing and repeated decantation from a dark-brown resin, and then left for some days to crystallise; and the product is purified by crystallisation from alcohol. Xanthorhamnin thus obtained forms compact tufts of pale-yellow shining crystals containing 5 at. water, which they give off without melting at 100°. In aqueous solution it is resinised by bromine and chlorine. Nitric acid oxidises it, forming a red solution which contains oxalic acid. It dissolves in strong sulphuric acid, and is thrown down as a yellow precipitate by water. By boiling with dilute acids, it is resolved into rhamnetin and glucose:

$$\underset{\text{Xanthorhamnin.}}{C^{23}H^{28}O^{14}} + 3H^{2}O = \underset{\text{Rhamnetin.}}{C^{11}H^{10}O^{5}} + \underset{\text{Glucose.}}{2C^{6}H^{12}O^{6}}.$$

Xanthorhamnin dissolves easily in water, either hot or cold, but cannot be separated from the solution in the crystalline form. It dissolves in cold alcohol, easily in boiling alcohol, but is insoluble in ether. With aqueous alkalis it forms brown solutions, which become paler when mixed with acids. It forms precipitates with salts of the alkaline earth-metals, aluminium-salts, and stannic salts. Neutral lead-acetate, mixed with an excess of alcoholic xanthorhamnin, gives a yellow precipitate, consisting, in the air-dried state, of $C^{23}H^{28}O^{14}.PbO$. Xanthorhamnin forms a black precipitate with iron-salts. It dyes fabrics mordanted with alumina, a fine yellow; those mordanted with iron, black. (Gellatly.)

Hlasiwetz (Ann. Ch. Pharm. cxi. 108) regards xanthorhamnin as identical with quercitrin (p. 6) and rhamnetin resulting from its decomposition as identical with quercetin (p. 4). This is doubted by Bolley (*ibid.* cxv. 55), who, however, obtained quercetin from Persian berries (Chem. Soc. Qu. J. xiii. 328); also by Gellatly (Chem. News, iii. 196; Jahresb. 1860, p. 497).

XANTHORRHŒA RESIN. Syn. with ACAROÏD RESIN (i. 2).

XANTHORTHITE. A yellow mineral from the Kullberg, near Stockholm, allied to orthite or allanite, and containing, according to Bahr (Berz. Jahresb. xxvi. 369), 32·93 per cent. SiO^2, 15·54 Al^2O^3, 4·21 FeO, 20·01 CeO (with LaO and DiO), 6·76 CaO, 0·59 YO, 2·15 MgO, 0·39 MnO, 17·55 water, and a small quantity of carbonic acid.

XANTHOSIDERITE. A hydrated ferric oxide, $Fe^2O^3.2H^2O$, occurring in acicular or fibrous crystalline groups, near Ilmenau in the Thuringian Forest. (E. Schmid, Pogg. Ann. lxxxiv. 495.)

XANTHOTANNIC ACID. The name given by Ferrein (Jahresb. 1858, p. 463) to the yellow colouring-matter of elm-leaves, which he regards as a tannic acid. The alcoholic extract of yellow elm-leaves gave, when treated with water, a yellow-brown liquid, from which acetate of lead threw down xanthotannate of lead, $3PbO.2C^{14}H^{18}O^2$.

XANTHOXYLENE. $C^{10}H^{16}$. (Stenhouse, Pharm. J. Trans. xvii. 19.)—The volatile oil of *Xanthoxylon piperitum*, Dec. (*Fagara piperita*, L.), the so-called Japan-pepper. It is colourless, strongly refractive, has an aromatic odour not altered by treatment with sodium; boils at 162°; forms a liquid compound with hydrochloric acid.

XANTHOXYLIN. (Stenhouse, Pharm. J. Trans. xiii. 423; xvii. 19.)—A crystalline non-nitrogenous camphor or stearoptene, which separates, on cooling, from the oil obtained by distilling the bruised seeds of *Xanthoxylon piperitum* with water. It may also be prepared by evaporating the alcoholic extract of the fruit; the crystals thus obtained are contaminated with resin, but may be purified by washing with cold aqueous ammonia, and recrystallising from alcohol or ether-alcohol.

Xanthoxylin forms monoclinic crystals, having a silky lustre, a faint odour, and a slight aromatic taste. It is insoluble in water, but dissolves easily in alcohol and ether, melts at 80°, solidifies at 78°, and may be distilled without decomposition. Nitric acid oxidises it to oxalic acid. The alcoholic solution is not precipitated by nitrate of silver, or acetate of lead, even on addition of ammonia.

XANTHOXYLON. The bark of *X. caribæum*, Lum., or *X. Clava Herculis*, L., used in the Antilles as a febrifuge, contains, according to Staples (Pharm. J. Trans. [2], iv. 399), a volatile oil, a green fixed oil, gum, and a crystallisable bitter principle, designated by him as xanthoxylin, and regarded by Bentley (*ibid.*), as probably identical with the xanthopicrite of Chevallier and Pelletan (p. 1053); according to Perrins, however, the two bodies are distinct, xanthopicrite being in fact identical with berberine.

The fruit of *X. piperitum* contains a volatile oil, xanthoxylene, and a crystalline camphor, xanthoxylin (*vid. sup.*)

XANTHURIN. The name given by Couerbe to a liquid compound, $C^4H^8SO^2$, which he supposed to be produced by the dry distillation of potassic or plumbic xanthate.

XANTHYDRIC ACID. Syn. with PERSULPHOCYANIC ACID (iv. 378).

XENOLITE. An aluminic silicate, occurring at Peterhof in Finland, in fibrous layers having a vitreous lustre, hardness = 7·0, and specific gravity = 3·5. Contains 47·44 per cent. silica, and 52·54 alumina. (Komonen, Pogg. Ann. lvi. 643.)

XENOTIME. Native phosphate of yttrium. (See PHOSPHATES, iv. 586.)

XENYLAMINE. $C^{12}H^{11}N = \left.\begin{matrix}C^{12}H^9\\H^2\end{matrix}\right\}N$. *Martylamine.* (Hofmann, Proc. Roy. Soc. xii. 389.)—A monamine isomeric with diphenylamine, occurring in the basic oil, boiling above 130°, which is obtained as a bye-product in the manufacture of aniline. This mixture of oily bases, neutralised with sulphuric acid, deposits impure sulphate of xenylamine, which may be purified by treating it with boiling alcohol, crystallising the remaining salt from a large quantity of boiling water, and again treating it with boiling alcohol. On suspending the pure sulphate thus obtained in weak alcohol, decomposing it with caustic soda, and adding water, xenylamine separates in the crystalline form, and may be purified by solution in alcohol, and precipitation with water.

Pure xenylamine forms white shining scales or needles, having a slight grey tint when dry. It is but slightly soluble in boiling water, easily in alcohol and in ether; melts at 45°, boils at 320°, and distils without decomposition. It unites with acids, forming crystallisable salts.—The *hydrochlorate*, $C^{12}H^{11}N.HCl$, forms white needles, somewhat more soluble than the sulphate.—The *chloroplatinate*, $2(C^{12}H^{11}N.HCl).PtCl^4.H^2O$, is a pale-yellow precipitate, composed of microscopic needles; does not give off its water of crystallisation at 150°.—The *nitrate*, $C^{12}H^{11}N.HNO^3$, forms large white needles, moderately soluble in water.—The *sulphate*, $(C^{12}H^{11}N)^2.H^2SO^4$, is distinguished by its sparing solubility in cold and even in boiling water; it is but little more soluble in boiling alcohol. From the boiling aqueous solution it separates in small needles.

Derivatives of Xenylamine.

Xenylamine shows less tendency than most other monamines to the formation of substitution-derivatives.—With *bromine, chlorine*, and most oxidising agents, it yields black compounds, which crystallise with difficulty, or not at all.—When *nitrous acid gas* is passed into an alcoholic solution of xenylamine, the liquid soon solidifies to a red crystalline mass, consisting of an azodixenylamine, $C^{24}H^{19}N^3 = C^{24}(H^{19}\overset{'''}{N})N^2$, or a double molecule of xenylamine, in which 3 at. H are replaced by 1 at. $\overset{'''}{N}$:

$$4C^{12}H^{11}N + N^2O^3 = 2C^{24}H^{19}N^3 + 3H^2O.$$

This body is insoluble in water, slightly soluble in alcohol, freely in ether. When treated with acids, it yields xenylamine, and an aromatic substance not yet examined.

Diethyl-xenylamine, $C^{16}H^{19}N = \left.\begin{matrix}C^{12}H^9\\(C^2H^5)^2\end{matrix}\right\}N$, is obtained in aqueous solution by treating xenylamine with ethylic iodide and silver-oxide alternately. On evaporating the solution, it crystallises in long white needles, insoluble in water, moderately soluble in alcohol, easily in ether; it has no alkaline reaction, melts below 100°, and volatilises without decomposition at a higher temperature. It forms crystallisable salts with hydrochloric, hydrobromic, and hydriodic acids.

Diethyl-xenylamine is not further acted upon by iodide of ethyl.—With *iodide of methyl*, however, it yields an ammonium-base, which has an alkaline reaction in the free state, and forms a crystalline chloroplatinate, $2C^{17}H^{22}NCl.PtCl^4 = 2(C^{12}H^9)(C^2H^5)^2(CH^3)NCl.PtCl^4$.

XENYLENE-DIAMINE. This name is given by Hofmann to benzidine $\left.\begin{matrix}(C^{12}H^8)''\\H^4\end{matrix}\right\}N^2$ (i. 545; iv. 411), which is, in fact, related to xenylamine in the same manner as ethylene-diamine (ii. 585) is related to ethylamine.

XENYLENIC ALCOHOL. $C^{12}H^{10}O^2 = \left.\begin{matrix}(C^{12}H^8)''\\H^2\end{matrix}\right\}O^2$. *Diphenyl-alcohol. Diphenylic Acid.* (Griess, Chem. Soc. J. xx. 96.)—A diatomic alcohol, produced by the action of water on nitrate of diazobenzidine (iv. 412):

$$C^{12}H^8N^4.2HNO^3 + 2H^2O = C^{12}H^{10}O^2 + 2HNO^3 + 2N^2.$$

It crystallises in small white or slightly coloured plates or needles, slightly soluble in water, freely in alcohol or ether. It melts when heated, and may be sublimed by cautiously heating small quantities of it in a test-tube. It dissolves easily in potash, and is precipitated therefrom by acids. Strong aqueous ammonia also dissolves it, and the solution gives a white bulky precipitate with acetate of lead. Strong nitric acid converts it into a nitro-acid, which crystallises in yellow roundish crystals, and forms an ammonium-salt crystallising in long needles.

XERASITE. A decomposing lava-mass containing hornblende, from Vesuvius.

XILITE. Syn. with XYLITE.

XILOPOL. Syn. with XYLOPOL.

XUTHENE. The sulphide of this radicle, $C^8H^7H^9S^2$, was supposed by Völckel to be produced, together with several other doubtful compounds, by the decomposition of persulphocyanic acid (iv. 379).

XYLENE, or **XYLOL,** C^8H^{10} = *Dimethylbenzene*, $C^6H^4(CH^3)^2$; isomeric with

Ethylbenzene, $C^6H^5(C^2H^5)$.—This hydrocarbon, homologous with benzene and toluene, was first obtained in the pure state from coal-naphtha by Hugo Müller (Zeitschr. Ch. Pharm. 1864, p. 161), its trinitro-compound having been previously prepared from Burmese naphtha by Warren De la Rue, and Hugo Müller in 1856 (Proc. Roy. Soc. viii. 225). It was afterwards prepared in larger quantity from coal-naphtha, and further examined by Beilstein, Wahlforss, and Rössler (Ann. Ch. Pharm. cxxxiii. 32; Jahresb. 1864, p. 529).—Fittig, in 1864 (Ann. Ch. Pharm. cxxxiii. 47), showed that it may be formed synthetically, as dimethylbenzene (methylbenzyl).

Xylene had been obtained, mixed with toluene and other hydrocarbons, several years before it was completely isolated. The hydrocarbon (boiling at 128°—130°), obtained by Cahours (Compt. rend. xxx. 319), and by Völckel (Ann. Ch. Pharm. lxxxvi. 335), was evidently a mixture of xylene and toluene; so likewise was the so-called xylene (boiling at 126·2°), prepared by Church (Chem. Soc. J. xiv. 52) from coal-naphtha. Nearly pure xylene had previously been obtained from coal-naphtha by Mansfield, Ritthausen, and Hilkenkamp; but they regarded it as cumene. The hydrocarbon, boiling at 145°—148°, and likewise described as cumene, separated by Cahours (Ann. Ch. Pharm. lxxvi. 286) from crude wood-spirit, and the so-called retinyl, boiling at 150°, obtained by Pelletier and Walter (*ibid.* xxiii. 150; xxviii. 297), from the distillation-products of the resin of *Pinus maritima*, also consisted mainly of xylene. Lastly, the hydrocarbon called petrol (iv. 383), found by Bussenius and Eisenstück in the petroleum of Sehnde near Hanover, is evidently identical with xylene.

Preparation.—1. From Coal-naphtha.—Light coal-naphtha, or (better) the least volatile portion of that which has been distilled off in benzene manufactories (boiling at 130°—160°), is subjected to repeated fractional distillation, to separate the portion which boils at about 141°; this portion is shaken up with oil of vitriol containing a little fuming sulphuric acid, which dissolves the xylene as xylene-sulphuric acid, leaving undissolved a small quantity of a hydrocarbon of the marsh-gas series (probably $C^{10}H^{22}$, boiling at 151°), and of another having the composition of turpentine; the xylene-sulphuric acid is decomposed by dry distillation; and the xylene which passes over is purified by washing, drying, and distillation. (Beilstein.)

2. By synthesis.—By the action of methylic iodide and sodium on monobromotoluene (Fittig):

$$\underset{\text{Bromotoluene.}}{C^6H^4Br.CH^3} + CH^3I + Na^2 = NaBr + NaI + \underset{\text{Xylene.}}{C^6H^4(CH^3)^2}.$$

Properties and Reactions.—Xylene is a colourless liquid, having a very faint odour, different from that of benzene. Specific gravity = 0·86 at 19°. Boils constantly at 139°. According to Warren (Jahresb. 1865, p. 514), its specific gravity is 0·8780 at 0°, 0·866 at 15°; boiling-point (corrected) 139·8°. By oxidation with potassic bichromate and sulphuric acid, it yields terephthalic acid, $C^8H^6O^4$; dilute nitric acid converts it into the intermediate product, toluic acid, $C^8H^8O^2$:

$$C^8H^{10} + O^3 = C^8H^8O^2 + H^2O.$$
$$C^8H^{10} + O^6 = C^8H^6O^4 + 2H^2O.$$

Probably, in the former case, toluic acid is first formed, and then further oxidated to terephthalic acid; in fact, toluic acid is actually transformed into terephthalic acid by oxidation with chromic acid. (Beilstein and De Scheffer, Zeitschr. f. Chem. 1865, p. 212.)

Xylene, passed in the state of vapour through a red-hot tube, is resolved into a mixture of several hydrocarbons—viz., benzene; toluene; a hydrocarbon, C^8H^8, probably styrolene; naphthalene; liquid hydrocarbons boiling between 250° and 320°; anthracene, $C^{14}H^{10}$, and probably its higher homologues; and, lastly, orange-coloured hydrocarbons of resinous and bituminous consistence, analogous to chrysene, benzerythrene, &c. The formation of these products may be represented by the following equations:

$$\underset{\text{Xylene.}}{C^8H^{10}} - H^2 = \underset{\text{Styrolene.}}{C^8H^8}$$
$$\underset{\text{Xylene.}}{3C^8H^{10}} = \underset{\text{Toluene.}}{2C^7H^8} + \underset{\text{Naphthalene}}{C^{10}H^8} + 3H^2.$$

The anthracene, $C^{14}H^{10}$, is produced by the dehydration of toluene. (Berthelot, Bull. Soc. Chim. 1867, i. 227.)

Ethylbenzene, $C^6H^5.C^2H^5$.—This hydrocarbon, isomeric with xylene, is produced by the action of sodium on a mixture of monobromobenzene and ethylic bromide. It is a colourless mobile liquid, very much like toluene, and boiling constantly at 133°. By oxidation with potassic bichromate and sulphuric acid, it yields benzoic acid.

Derivatives of Xylene.

The chlorine- and bromine-derivatives of xylene have not been much investigated. Theoretically, they should exhibit isomeric modifications, similar to those of the toluene-derivatives (p. 852), but in greater number, inasmuch as xylene contains two atoms of methyl, whereas toluene contains only one. Thus there should be two xylylic chlorides corresponding to benzylchloride, the one being isomeric with monochloroxylene, the other with dichloroxylene; thus—

Monochloroxylene, $C^6H^2Cl\left\{\begin{matrix}CH^3\\CH^3\end{matrix}\right.$, isomeric with $C^6H^4\left\{\begin{matrix}CH^3\\CH^2Cl\end{matrix}\right.$, first chloride.

Dichloroxylene, $C^6H^2Cl^2\left\{\begin{matrix}CH^3\\CH^3\end{matrix}\right.$ „ „ $C^6H^4\left\{\begin{matrix}CH^2Cl\\CH^2Cl\end{matrix}\right.$, second chloride.

From experiments by Körner, it appears that both these chlorides are produced when xylene is treated with chlorine at the boiling heat.

Bromo-xylenes. (Riche and Bérard, Ann. Ch. Pharm. cxxxiii. 53.—Beilstein and Wahlforss, *ibid.* 46.—Fittig and Ernst, Zeitschr. Ch. Pharm. 1865, p. 572.) —When bromine is made to flow slowly into xylene, a large quantity of hydrobromic acid escapes, and the colour of the bromine disappears almost immediately. On shaking up the product with potash-ley, distilling over caustic potash (best with addition of a little alcohol, to prevent percussive ebullition), and purifying by fractional distillation, monobromoxylene, C^8H^9Br, is obtained as a colourless liquid, of specific gravity 1·335 at 20°, boiling at 212° (Wahlforss), at 203°—204° (Fittig and Ernst), at 203° (Kekulé). Its vapour does not excite tears.

The more highly brominated derivatives of xylene are produced in small quantity by the process just described (Kekulé). Riche and Bérard, by treating xylene with bromine for several days, obtained an oily product, which was converted by nitric acid into a crystallisable nitro-compound, $C^8H^6Br^3(NO^2)$; the bromine-compound was therefore tribromoxylene, $C^8H^7Br^3$.

Ethylbenzene is slowly attacked by bromine, forming monobromo-ethylbenzene, which is a liquid boiling at about 200°. When heated with bromine to 100°, it yields more highly brominated compounds, which are also liquid. (Fittig, Ann. Ch. Pharm. cxxxiii. 226.)

Chloro-xylenes. (Hollemann, Zeitschr. f. Chem. 1865, p. 554; Jahresb. 1865, p. 554.—Vollrath, Zeitschr. f. Chem. 1866, p. 488; Jahresb. 1866, p. 605.—Lauth and Grimaux, Bull. Soc. Chim. 1867, i. 233; Ann. Ch. Pharm. cxlv. 115.)

Monochloro-xylene, $C^6H^3Cl(CH^3)^2$, has not yet been obtained; but the isomeric compound, toluylic chloride, or chloride of toluyl, $C^6H^4\left\{\begin{matrix}CH^3\\CH^2Cl\end{matrix}\right.$, is produced by the action of chlorine on xylene at the boiling heat (Vollrath, p. 870), or by passing chlorine-gas into vapour of xylene, and subjecting the product to repeated fractional distillation (Lauth and Grimaux). It is a clear colourless liquid, which excites a copious flow of tears; boils between 190° and 195° (Lauth and Grimaux); at 193° (Vollrath). It precipitates a solution of *silver-nitrate* even in the cold, and when boiled with acetate of silver, yields chloride of silver and acetate of toluyl (p. 869). Heated for an hour with ½ mol. *nitrate of lead* and 6 or 7 times its weight of water, it is converted into toluic aldehyde, C^8H^8O (Lauth and Grimaux). It is decomposed by *sodium*, yielding toluyl, $(C^8H^9)^2$, and when treated with *cyanide of potassium*, in presence of alcohol, it yields alphaxylylic acid, $C^9H^{10}O^2$. (Vollrath.)

Dichloro-xylene, $C^8H^8Cl^2 = C^6H^2Cl^2\left\{\begin{matrix}CH^3\\CH^3\end{matrix}\right.$, is produced by passing chlorine, nearly in the quantity required by theory, into xylene containing a small quantity of iodine, and purifying the product by fractional distillation. It crystallises in white laminæ, melts at the heat of the hand, and boils at 222°; dissolves easily in alcohol and in benzene. It does not exhibit double decomposition with acetate or cyanide of potassium, even at 120°.—*Sodium* attacks it readily, producing a solid hydrocarbon, not yet examined. (Hollemann.)

The same or an isomeric compound is produced, together with the monochlorinated compound, in the process just described, and is deposited in the solid form when the portions of the crude product which distil over between 230° and 240°, and between 240° and 250°, are cooled by a freezing mixture. It may be purified by pressure, and crystallises by slow evaporation from a large quantity of ether, or a mixture of ether and alcohol, in rather large, transparent, shining crystals. It melts at 100°, and solidifies to a radiate mass on cooling; distils between 240° and 245°, being for the most part decomposed at the same time. (Lauth and Grimaux.)

Trichloro-xylene, $C^8H^7Cl^3$, is easily produced by passing chlorine into xylene mixed with iodine, till the mass becomes solid. It boils at 254°—256°, and forms white silky needles, easily soluble in warm alcohol and benzene, sparingly in the same liquid when cooled. (Hollemann.)

Ethyl-xylene, $C^{10}H^{14} = C^8H^9(C^2H^5) = C^6H^3(CH^3)^2(C^2H^5)$, is produced (like ethyltoluene, p. 857) by the action of sodium on a mixture of monobromoxylene and ethylic bromide. It is a liquid having a specific gravity of 0·8783 at 30°, and boiling at 183°—184°. When warmed with nitrosulphuric acid, it is converted into a trinitro-compound, crystallising from alcohol in needles, and melting at 119°. By oxidation with chromic acid, it yields an acid resembling terephthalic acid, but more easily soluble in alcohol. (Fittig and Ernst, Ann. Ch. Pharm. cxxxix. 184.)

Methyl-xylene, $C^9H^{12} = C^8H^9(CH^3) = C^6H^3(CH^3)^3$, prepared in like manner, boils at 165°—166°, and unites with a small quantity of bromine (with evolution of hydrobromic acid), forming a solid bromide, which crystallises from alcohol in laminæ, melts at 73°, and is identical with bromide of cumene. The barium-salt of the sulpho-acid of methyl-xylene reacts also exactly like cumene-sulphate of barium. (Fittig and Ernst.)

Nitro-xylenes. (Müller, Zeitschr. Ch. Pharm. 1864, p. 161.—Beilstein, Ann. Ch. Pharm. cxxxiii. 45.—Fittig, *ibid.* cxxxiii. 48.—Glinzer and Fittig, *ibid.* cxxxvi. 307.—Deumelandt, Zeitschr. f. Chem. 1866, p. 21.)—When xylene (either from coal-naphtha, or prepared synthetically) is dissolved in cold fuming nitric acid, and water is added to the solution, a heavy oil separates out, consisting chiefly of mononitroxylene, but often depositing crystals of dinitroxylene after long standing.—*Mononitroxylene*, $C^8H^9(NO^2)$, is a liquid, and when pure distils without decomposition; on distilling the crude product, however, explosive decomposition takes place towards the end, arising from admixed dinitroxylene. Mononitroxylene boils at 240°. (Deumelandt.)

Dinitro-xylene, $C^8H^8(NO^2)^2$, is solid, and crystallises from dilute alcohol in highly lustrous crystals, which melt at 93°. From synthetically-prepared xylene, Fittig and Glinzer obtained, together with the dinitroxylene just described, an isomeric modification, melting at 123·5°.

Trinitro-xylene, $C^8H^7(NO^2)^3$, is easily produced by the action of a mixture of nitric and sulphuric acids upon xylene, by prolonged contact at ordinary temperatures, more quickly when heated. It is solid, and slightly soluble in cold alcohol; from boiling alcohol it crystallises in needles which melt at 177° (Beilstein). By the action of reducing agents it is converted into dinitroxylidine or nitroxylene-diamine (p. 1059).

The compound $C^8H^7(NO^2)^3$, described (iv. 382) as *trinitropetrol*, melts at 162°.

By the action of nitrosulphuric acid on synthetically-prepared xylene, and on the two modifications of dinitroxylene, Glinzer and Fittig obtained crystallisable trinitroxylene melting at 137°.

Ethylbenzene, $C^6H^5(C^2H^5)$, dissolves easily and with violent action in cooled fuming nitric acid, and water added to the solution throws down mononitro-ethylbenzene, $C^8H^9(NO^2)$, which distils without decomposition at 233°. At ordinary temperatures the nitration does not proceed any further; but on warming the liquid, or on dropping ethylbenzene into a warmed mixture of 2 vols. sulphuric and 1 vol. nitric acid, and adding water, dinitro-ethylbenzene, $C^8H^8(NO^2)^2$, separates as a non-distillable oil. This compound, boiled for an hour with nitrosulphuric acid, is converted into trinitro-ethylbenzene, $C^8H^7(NO^2)^3$, which is also a non-distillable oil.

Azo-xylene, C^8H^9N, or $C^{16}H^{18}N^2$.—Produced by the action of sodium-amalgam on nitroxylene. Crystallises in brick-red needles, which melt at 120°, and volatilise without decomposition. If the treatment with sodium-amalgam be further continued, colourless crystals are obtained, which dissolve very easily in alcohol and ether, and sublime even when the ethereal solution is evaporated: they probably consist of hydro-azoxylene, $C^{16}H^{20}N^2$. (Werigo, Zeitschr. f. Chem. 1864, p. 723; 1865, p. 312.)

XYLENE-DIAMINE. Syn. with XYLYLENE-DIAMINE (p. 1061).

XYLENE-SULPHOCHLORIDE. $C^8H^9SClO^2 = C^6H^3(CH^3)^2.SO^2Cl$. (Yssel de Scheffer, Zeitschr. f. Chem. 1865, p. 360.)—This compound is obtained, as a yellow non-distillable oil, by triturating xylene-sulphate of sodium with pentachloride of phosphorus, warming the mixture, and pouring the product into water. By the action of zinc and sulphuric acid, it is reduced to xylene-sulphydrate; when treated in ethereal solution with sodium-amalgam, it is converted into xylene-sulphurous acid.

XYLENE-SULPHURIC ACID. $C^8H^{10}SO^3 = C^8H^9.SO^3H = C^6H^3(CH^3)^2.SO^3H$. *Xylolsulphuric Acid. Sulphoxylolic Acid. Xylylsulphurous Acid.* (Church, Jahresb. 1855, p. 634.—Beilstein and Wahlforss, Ann. Ch. Pharm. cxxxiii. 38.—

Fittig and Glinzer, *ibid.* cxxxvi. 305.)—This compound (partly described as xylylsulphurous acid, p. 505) is produced by the action of strong sulphuric acid on xylene; if the mixture be warmed in the water-bath, and frequently shaken with fuming sulphuric acid, the action is quicker.

Xylene-sulphuric acid is crystallisable, and extremely soluble in water: by dry distillation it yields xylene.—Its *potassium-salt* is easily soluble in water and in alcohol, and crystallises from alcohol in silky laminæ.—The *barium-salt*, $C^8H^9.Ba''(SO^3)^2.H^2O$, forms spherical groups of shining scales, very soluble in water, and giving off their water of crystallisation over oil of vitriol.—The *calcium-*, *lead-*, and *copper-salts* are very soluble in water and in alcohol.

Amidoxylene-sulphuric Acid, $C^8H^8(NH^2).SO^3H = C^6H^2(NH^2)(CH^3)^2.SO^3H$.—*Xylidine-sulphuric Acid.*—Obtained by heating sulphate of xylidine with sulphuric acid. Crystallises from dilute aqueous solution in needles, and is so sparingly soluble in water that it may be precipitated from its salts.—The *barium-salt* forms nodules easily soluble in water. (Deumelandt, Zeitschr. f. Chem. 1866, p. 22.)

XYLENE-SULPHUROUS ACID. $C^8H^{10}SO^2 = C^8H^9.SO^2H = C^6H^3(CH^3)^2.SO^2H$.—A viscid uncrystallisable oil, produced by the action of sodium-amalgam on an ethereal solution of xylene-sulphochloride. (Otto, Zeitschr. f. Chem. 1866, p. 583.)

XYLENE-SULPHYDRATE. $C^8H^{10}S = C^8H^9.SH = C^6H^3(CH^3)^2.SH$. *Xylolsulphydrate. Xylylsulphydrate. Xylylic Mercaptan.* (Yssel de Scheffer, Zeitschr. f. Chem. 1865, p. 360.)—Produced by the action of zinc and sulphuric acid on xylene-sulphochloride. It is a colourless, strongly refracting oil, insoluble in water, soluble in alcohol and in ether. Boils at 213°.—Its *mercury-compound* crystallises from alcohol in white scales having a silky lustre.—The *lead-salt* is precipitated from alcoholic solutions as a powder of a fine yellow colour.—The *copper-* and *silver-salts* are pale-yellow unstable precipitates.

Xylene-sulphydrate is strongly attacked by bromine and by pentachloride of phosphorus, probably forming disulphide of xylene.

XYLENYL. Syn. with XYLYL (p. 1061).

XYLENYLAMINE.
XYLIDAMINE. } Syn. with XYLIDINE.

XYLIDINE. $C^8H^{11}N = C^8H^9(NH^2)$. *Amidoxylene. Amidoxylol.* (Church, Phil. Mag. [4], lx. 256.—Deumelandt, Zeitschr. f. Chem. 1866, p. 21.)—This base, homologous with aniline, toluidine, and cumidine, and isomeric with ethylaniline, dimethylaniline, and collidine, is produced by the action of sulphide of ammonium, ferrous acetate, or stannous chloride on nitroxylene. When this nitro-compound is treated with tin and hydrochloric acid, the whole solidifies on cooling to a crystalline mass, consisting of a compound of hydrochlorate of xylidine with stannous chloride, which, by recrystallisation from strong hydrochloric acid, may be obtained in large scaly crystals. By decomposing this compound with sulphuretted hydrogen, and evaporating the filtrate, crystallised hydrochlorate of xylidine is obtained, which forms an easily decomposible double salt with platinic chloride.

Free xylidine may be obtained by distilling the hydrochlorate with dry soda—or (better) by reducing nitroxylene with iron and acetic acid, and distilling the product with excess of soda-ley. The base thus obtained may be combined with hydrochloric acid, and precipitated by potash from this salt, after it has been purified by recrystallisation.

Xylidine is a colourless liquid, heavier than water, and boiling at 214° to 216°.—*Nitrate of xylidine* crystallises in white silky laminæ; the *sulphate* and *oxalate* are also crystallisable.

Dinitroxylidine, $C^8H^7(NO^2)^2.NH^2$, is produced, together with nitroxylylene-diamine (p. 1061), by the action of ammonium-sulphide on trinitroxylene (Beilstein, Ann. Ch. Pharm. cxxxiii. 45). It is identical with the yellow base obtained by Bussenius and Eisenstück as a bye-product in the reduction of trinitroxylene (trinitropetrol) from the petroleum of Sehnde (iv. 382, footnote). On dissolving out the nitroxylylene-diamine with dilute hydrochloric acid, the dinitroxylidine remains behind, and must be freed from sulphur by recrystallisation from alcohol. It is yellow, insoluble in water, alkalis, and dilute acids, soluble in hot concentrated acids; but is separated, in the pulverulent form, from these solutions on addition of water. From alcoholic solution it separates, by very slow cooling, in needle-shaped crystals, which melt at 191°—192°.

XYLIDINE-SULPHURIC ACID. Syn. with AMIDOXYLENE-SULPHURIC ACID.

XYLITE. This name is given by Hermann (Bull. Soc. d. Sc. nat. de Moscou, i. 247) to a mineral containing 44 per cent. SiO^2, 38·22 Fe^2O^3, 6·1 CuO, 4·8 MgO, 0·68 CuO, and 4 44 water, forming finely fibrous masses resembling mountain-wood, of specific gravity 2·935.

XYLITE of Weidmann and Schweizer. Syn. with Lignone (iii. 694).

XYLOBALSAMUM. The commercial name of the odoriferous wood of *Amyris gileadensis*, which yields Mecca balsam (i. 495).

XYLOCHLOERIC ACID. A term applied by Fordos (Compt. rend. lvii. 50) to the green colouring-matter of decayed wood, which may be extracted by chloroform.

XYLOCHLORE. A mineral found in a fossil tree-stem from the volanic tufa near Husavik in Iceland, forming olive-green quadratic pyramids, and containing 52·07 SiO^2, 1·54 Al^2O^3, 20·57 CaO, 0·33 MgO, 3·4 FeO, 0·55 Na^2O, 3·77 K^2O, and 17·14 water (Sartorius v. Waltershausen, Vulcan. Gest. Islands, p. 297). Kenngott (J. pr. Chem. lxxxix. 455) has shown that it is an altered form of apophyllite.

XYLOCRYPTITE. A mineral apparently related to Scheererite, occurring in yellow waxy crystalline particles on lignite. (Becquerel.)

XYLOÏD. Löwig's name for the radicle xylyl, C^8H^9.

XYLOÏDIC ACID. See the next article.

XYLOÏDIN. $C^6H^9NO^7 = C^6H^9(NO^2)O^5$. *Pyroxam. Nitramidin. Explosive Starch.* (Braconnot, Ann. Ch. Phys. [2], lii. 290.—Liebig, Ann. Ch. Pharm. vii. 249.—Payen, N. Ann. Sc. nat. Bot. x. 161.—Pelouze, Compt. rend. vii. 713; xxiii. 890.—Gladstone, Mem. Chem. Soc. iii. 412.—Bouijs-Ballot, Ann. Ch. Pharm. xlv. 47.—Béchamp, Ann. Ch. Phys. [3], xlvi. 338; lxiv. 311.—Gm. xv. 106.)—This compound, discovered by Braconnot in 1833, is produced by the action of strong nitric acid upon starch. To prepare it, starch is triturated in a thick porcelain mortar (to prevent rise of temperature) with 5 to 8 pts. of fuming nitric acid, till it is reduced to a transparent semifluid mass, without evolution of gas; and 20 to 30 pts. of water are then added, whereupon the xyloïdin is precipitated as a white granular mass, while a small quantity of starch remains in solution. If the action of the acid be too much prolonged, the liquid becomes coloured, nitric oxide is given off, and no precipitate is obtained on subsequent addition of water: but the liquid then contains a deliquescent uncrystallisable acid (called *xyloïdic acid*, but probably identical with saccharic acid). (Pelouze, Béchamp.)

To purify the xyloïdin, it is dissolved, after washing and drying, in a mixture of 10 pts. glacial acetic acid, ($C^2H^4O^2$), and 1 pt. of the dihydrated acid, ($C^2H^4O^2.2H^2O$), and the solution is filtered and evaporated. 100 pts. starch thus treated yield from 128 to 130 pts. of xyloïdin. (Béchamp.)

Xyloïdin is a white, inodorous, and tasteless powder, which does not redden litmus. It is insoluble in water, alcohol, ether, chloroform, ethylic acetate, acetone, and benzene; dissolves in glacial acetic acid to a thick mucilage, more easily, according to Béchamp, on addition of $\frac{1}{10}$ of the dihydrated acid; the solution coagulates on addition of water. In boiling water, xyloïdin cakes together without dissolving.

Xyloïdin when struck decomposes with detonation, but not so violently as guncotton. It melts when heated, and takes fire at 180°, burning brightly, and leaving a carbonaceous residue. Gladstone found that a sample which had been kept for six years, decomposed suddenly, with evolution of gas containing a large proportion of hydrocyanic acid, and after some weeks a somewhat tenacious residue remained behind.

Bromine does not act upon xyloïdin.—*Iodine* colours it yellow.—Strong *nitric acid* dissolves it, with decomposition, after some time.—Strong *sulphuric acid* dissolves it with blackening, and on adding water the xyloïdin separates out: dilute sulphuric acid does not dissolve it.—In strong *hydrochloric acid* it dissolves without decomposition, and is precipitated by water in its original state.—It is partially dissolved by *potash*.—*Ferrous salts* decompose it, with evolution of nitric oxide and production of soluble starch:

$$\underset{\text{Xyloïdin.}}{2C^6H^9(NO^2)O^5} + 6FeCl^2 + H^2O = Fe^2O^3 + 2Fe^2Cl^6 + 2NO + \underset{\text{Starch.}}{2C^6H^{10}O^5}.$$

The starch may be precipitated from the resulting solution by alcohol, and thus obtained in a state of purity.

Soluble Xyloïdin, Isoxyloïdin, or *Isonitramidin.*—This modification of xyloïdin is obtained by treating starch with excess of strong nitric acid (10 to 12 pts.), precipitating the yellow gummy solution with water, dissolving the dried precipitate in ether-alcohol, and evaporating the filtrate. The product thus obtained resembles xyloïdin in composition, and in many of its properties, but is distinguished therefrom by being perfectly soluble in pure alcohol, wood-spirit, acetone, ether, a mixture of ether and alcohol, and in ethylic acetate; in alcohol of 95 per cent. it is insoluble. (Béchamp, Ann. Ch. Phys. [3], lxiv. 320.)

Nitroxyloïdin, or *Dinitramidin*, $C^6H^8(NO^2)^2O^5$, is produced, also in a more soluble and less soluble modification, by the action of strong sulphuric acid on xyloïdin or isoxyloïdin. To prepare it, 1 pt. of dry starch is dissolved in 12 pts. fuming nitric acid, and the solution (filtered, if necessary, through pounded glass) is placed in a freezing mixture, and quickly mixed with 8 pts. oil of vitriol; the soft white mass thereby separated is quickly mixed with a large quantity of cold water; and the product, which is a white powder resembling xyloïdin, is well washed, and dried in a hot-air chamber. This product is chiefly a mixture of nitroxyloïdin and isonitroxyloïdin, which may be separated from one another by digestion with alcohol of 96 per cent., first in the cold, then at 40°, whereby the isonitroxyloïdin is dissolved, and the nitroxyloïdin remains behind.

Nitroxyloïdin is a white easily pulverised mass, which decomposes much more readily than xyloïdin, and is reduced by ferrous salts in the same manner as the latter, yielding soluble starch. It is insoluble in water and in alcohol, but soluble in pure ether, and in alcoholised ether; soluble in glacial acetic acid, but insoluble in a mixture of the glacial and dihydrated acid, exhibiting, in this respect, exactly the opposite relation to xyloïdin.

Isonitroxyloïdin is insoluble in water, soluble in alcohol of 96 per cent., dissolves with difficulty in ether, but easily in a mixture of ether and alcohol. It is even more prone to spontaneous decomposition than the less soluble modification.

XYLOL. Syn. with XYLENE.

XYLOLITE. Syn. with mountain-wood, or ligniform asbestos (i. 415).

XYLOLSULPHURIC ACID. Syn. with XYLENE-SULPHURIC ACID (p. 1058).

XYLOLSULPHYDRATE. Syn. with XYLENE-SULPHYDRATE (p. 1059).

XYLONES, CHLORINATED. This term was applied by Gorup-Besanez (Ann. Ch. Pharm. lxxxvi. 237), to various chlorinated products, formed by treating the creosote of beechwood tar with potassic chlorate and hydrochloric acid: they are not, however, related in any way to xylene.

XYLORETIN. $C^{10}H^{16}O$.—A crystalline resin, isomeric or polymeric with camphor, occurring in fossil pine-trunks. It is insoluble in water, easily soluble in alcohol and ether, and crystallises from the ethereal solution in white masses; melts at 165°; cannot be volatilised without decomposition. It unites with bases, without separation of water. Heated with *potassium*, it gives off hydrogen, and forms a potassium-compound, which dissolves in alcohol and crystallises therefrom.

XYLOSTEIN. See the next article.

XYLOSTEUM. The berries of the fly honeysuckle (*Lonicera Xylosteum*) were formerly used medicinally as *Baccæ xylostei*: they are said to be narcotic. They contain 86·4 per cent. water, 2·3 substances soluble in ether, 6·2 soluble in alcohol, and 2·9 soluble in water. The fresh berries yield 1 per cent. ash, containing (in 100 pts.) 22·8 K^2O, 9·5 Na^2O, 23·5 CaO, 8·2 MgO, 0·8 Al^2O^3 and Fe^2O^3, 4·8 SO^3, 16·2 P^2O^5, 2·9 SiO^2, 1·3 Cl, and 10·0 CO^2 (Enz, Chem. Centralbl. 1856, p. 393).—According to Hübschmann (Arch. Pharm. lxxxv. 250), the berries contain a peculiar, non-volatile, bitter principle, xylostein, soluble in alcohol and ether, insoluble in water. According to Enz, this body is a glucoside, yielding sugar when decomposed by acids.

XYLOTIL. Syn. with MOUNTAIN-WOOD (i. 415).

XYLYL. C^8H^9.—A monatomic radicle, homologous with phenyl and tolyl, which may be supposed to exist in xylene ($C^8H^9.H$) and its derivatives.

XYLYLAMINE. This name belongs to a base, $C^8H^9.H^2.N = C^6H^4\left\{\begin{matrix}CH^3\\CH^2(NH^2)\end{matrix}\right.$ (not yet obtained), related to benzylamine, $C^7H^7.H^2.N$ (p. 807), in the same manner as xylidine, $C^8H^9(NH^2) = C^6H^3(NH^2)\left\{\begin{matrix}CH^3\\CH^3\end{matrix}\right.$ to toluidine, $C^6H^4(NH^2).CH^3$ (p. 852).

XYLYLATES. See XYLYLIC ACID (p. 1062).

XYLYLENE. C^8H^8.—A diatomic radicle related to xylyl, C^8H^9, in the same manner as ethylene to ethyl.

XYLYLENE-DIAMINE, $C^8H^{12}N^2 = \begin{matrix}(C^8H^8)''\\H^4\end{matrix}\Big\} N^2$, or *Diamido-xylene*, $C^8H^8(NH^2)^2$, is formed by reducing dinitroxylene with tin and hydrochloric acid; its hydrochlorate, treated with bromine, yields the hydrochlorate of bromoxylylene-diamine, $C^8H^7Br.(NH^2)^2$.

Nitroxylylene-diamine, or *Nitro-diamidoxylene*, $C^8H^7(NO^2)(NH^2)^2$, is the compound already described as nitropetrol-diamine, which Bussenius and

Eisenstück obtained by reducing the so-called trinitropetrol with sulphide of ammonium (iv. 382).

XYLYLIC ACID. $C^9H^{10}O^2 = C^6H^3(CH^3)^2.CO^2H$. (Kekulé, Bull. Soc. Chim. 1866, ii. 47.—Hirzel and Beilstein, *ibid.* 1867, i. 345.)—This acid, homologous with benzoic and toluic acids, is produced:—1. By the action of sodium and carbonic anhydride on bromoxylene (Kekulé):

$$\underset{\text{Bromo-xylene.}}{C^8H^9Br} + Na^2 + CO^2 = NaBr + \underset{\text{Xylylate of sodium.}}{C^8H^9.CO^2Na.}$$

The process is conducted as for the preparation of toluic acid from toluene (p. 862), the bromoxylene being diffused through a hydrocarbon boiling at about 120°.—2. By oxidising cumene (C^9H^{12}) with potassic bichromate and sulphuric acid, or (better) with dilute nitric acid. (Beilstein and Kögler, Ann. Ch. Pharm. cxxxvii. 317; Jahresb. 1865, p. 559.)

Cumene oxidised with dilute nitric acid yields first xylylic acid, and afterwards insolinic acid, [$C^9H^8O^4 = C^6H^3(CH^3)(CO^2H)^2$]. To prepare xylylic acid, cumene is treated with nitric acid diluted with twice its volume of water; and the acid product is treated with tin and hydrochloric acid, to decompose the nitro-acids formed at the same time. On distilling the product with water, xylylic acid passes over, while insolinic acid remains behind. If the cumene employed is not pure, an oily product distils over at the same time; in that case the receiver must be changed as soon as crystalline xylylic acid begins to pass over. (Hirzel and Beilstein.)

Xylylic acid is insoluble in cold water (Kekulé); very slightly soluble (Hirzel and Beilstein). It dissolves sparingly in boiling water, and separates on cooling in white needles; dissolves very easily in alcohol and ether (Kekulé). According to Hirzel and Beilstein, it melts in boiling water; in the dry state it melts at 103°, and boils at 273°. It sublimes easily in needles (Kekulé). Xylylic acid is quickly oxidised by chromic acid, and converted into insolinic acid, $C^9H^8O^4$. (Hirzel and Beilstein.)

Xylylate of Barium, $(C^9H^9O^2)^2Ba''.4H^2O$, crystallises in shining colourless laminæ.—The *calcium-salt*, $(C^9H^9O^2)^2Ca''.3H^2O$, forms stellate groups of shining needles.—The *ethylic ether*, $C^9H^9(C^2H^5)O^2$, is an aromatic oil, boiling at 233°. (Hirzel and Beilstein.)

Alphaxylylic Acid, $C^9H^{10}O^2 = C^6H^4\left\{\begin{matrix}CH^3\\CH^2.CO^2H\end{matrix}\right.$ (Vollrath, Zeitschr. f. Chem. 1866, p. 488; Jahresb. 1866, p. 605.)—This acid, homologous with alphatoluic acid (p. 863), is formed by boiling toluylic chloride, C^8H^9Cl (p. 870), in alcoholic solution with cyanide of potassium, and then with potash:

$$\underset{\text{Toluylic chloride.}}{C^6H^4\left\{\begin{matrix}CH^3\\CH^2Cl\end{matrix}\right.} + CNK + 2H^2O = KCl + NH^3 + \underset{\text{Alphaxylylic acid.}}{C^6H^4\left\{\begin{matrix}CH^3\\CH^2.CO^2H.^*\end{matrix}\right.}$$

It may be precipitated from the resulting solution by an acid, and, when purified by boiling with milk of lime, crystallises in broad needles, having a satiny lustre, melting at 42°, and dissolving very readily in water.

XYLYLIC ACETATE, CHLORIDE, &c. Syn. with TOLUYLIC ACETATE, CHLORIDE, &c. (pp. 870, 871).

XYLYLIC ALCOHOLS. $C^8H^{10}O$.—This formula may include several isomeric compounds, but only three have hitherto been investigated with any approach to accuracy:—

1. The compound described (p. 869) as toluylic alcohol, $C^8H^9.OH$ or $C^6H^3(CH^3)^2.OH$, which would be better called xylylic alcohol, inasmuch as it is obtained directly from the chloride, $C^8H^9.Cl$ (chloride of xylyl), produced by the action of chlorine on xylene at high temperatures. This alcohol is the homologue of benzylic or tolylic alcohol, $C^7H^7.HO$ (i. 578).

2. The compound called phlorol, phloretol, or phlorylic alcohol, which Hlasiwetz obtained by distilling barium-phloretate with lime (iv. 493). This compound is a true homologue of phenol, probably ethyl-phenol, $C^6H^4(C^2H^5).OH$.

3. The "xylylic phenol," mentioned by H. Müller (Zeitschr. f. Chem. 1865, p. 271) as occurring in coal-tar. This is probably dimethyl-phenol, $C^6H^3(CH^3)^2.OH$, inasmuch as products obtained by dry distillation have hitherto been found to contain only methyl-derivatives of benzene. The portion of aloïsol (the product obtained by distilling aloes with lime, i. 148), which is soluble in potash, has also, according to

---

[*] This is the formula of insolinic acid originally given by Hofmann (p. 725). According to Hirzel and Beilstein, insolinic acid is very much like terephthalic acid, but dissolves very easily in boiling water. It does not yield any higher oxidation-products when treated with chromic acid.

Rembold (Ann. Ch. Pharm. cxxxviii. 186), the composition of a xylylic alcohol, and is, perhaps, identical with the last mentioned.

XYLYLIC MERCAPTAN. Syn. with Xylene-sulphydrate (p. 1059).

XYLYLSULPHAMIC ACID, $C^8H^{11}NSO^3$, is produced by heating sulphate of xylidine with sulphuric acid, and crystallises in needles very slightly soluble in cold water.—Its *barium-salt*, $(C^8H^{10}NSO^3)^2Ba''$, is very soluble, and crystallises in nodular groups. (Deumelandt, Bull. Soc. Chim. 1866, ii. 211.)

XYLYLSULPHUROUS ACID. Syn. with Xylene-sulphuric Acid (p. 1058).

XYLYLSULPHYDRATE. Syn. with Xylene-sulphydrate (p. 1059).

Y

YABICOJA. An ore occurring, with atacamite and quartz, in the district of Tarapaca in Peru. (Leonh. Jahrb. p. 243.)

YAM. See Dioscorea (ii. 335).

YANOLITE, or **YANTHOLITE.** Syn. with Axinite (i. 477).

YEAST. See Fermentation (ii. 629).

YELLOW COPPER-ORE. Syn. with Copper Pyrites (ii. 77).

YELLOW COPPERAS. Syn. with Botryogen (i. 651).

YELLOW DYES. See Dyeing (ii. 356).

YELLOW LEAD-ORE. Native molybdate of lead, or wulfenite. (See Molybdenum, iii. 1039.)

YELLOW METAL. An alloy of 60 pts. copper and 40 pts. zinc; also called Muntz's metal. (See Copper, Alloys of, ii. 49.)

YELLOW OCHRE. See the next article.

YELLOW PIGMENTS. The yellow pigments mostly employed as artists' colours are *sulphide of cadmium* (i. 706), *gamboge* (ii. 770), *Indian yellow*, which consists mainly of euxanthate of magnesium (ii. 609), and *yellow ochre*, which consists of clay or marl coloured with ferric oxide.—*Chrome-yellow*, or neutral chromate of lead, is used chiefly for carriage-painting; also for colouring wall-papers, and as an ingredient in yellow varnishes; it is never used alone, but always mixed with chromate of calcium or barium, or sulphate of lead. A mixture of chromate of lead with the sulphates of lead and calcium constitutes *Cologne yellow*. Other yellow lead-salts are also used as pigments, chiefly for house-decoration and paper-staining—viz., certain oxychlorides of lead (iii. 556), known as *Turner's yellow, Cassel yellow*, &c.; a basic sulphate, $PbSO^4.PbO$, known in France as *jaune paille mineral*, and prepared by fusing a mixture of neutral sulphate and oxide of lead; *Naples yellow*, a basic antimoniate of lead (i. 326), used as an artists' colour, in oil-painting; and less frequently, *iodide of lead*, which has a fine colour, but is somewhat fugitive; and *arsenate of lead*, which is objectionable on account of its poisonous character. All these lead-yellows cover well, but have the inconvenience of turning brown or black on exposure to sulphuretted hydrogen.—*Chromate of zinc*, prepared by precipitation, has a fine colour, much like that of chromate of lead, and is not affected by sulphuretted hydrogen.—The *chromates of barium* and *calcium* are used for colouring paper-hangings, also for mixing with chromate of lead. (Lefort, *Chimie des Couleurs*, 1855.)

YELLOW PODS. The pods of *Gardenia grandiflora*, which yield crocin (ii. 108).

YELLOW TELLURIUM. Syn. with Sylvanite (p. 647).

YENITE. Syn. with Lievrite (iii. 589).

YERBA MATÉ. Syn. with Paraguay Tea (iv. 349).

YPADU-PLANT. Syn. with Coca (i. 1059).

YTTERBITE, YTTERITE. Syn. with Gadolinite (ii. 757).

YTTRIA. Oxide of yttrium (p. 1064).

YTTRITE. Syn. with Gadolinite.

YTTRIUM. *Symbol*, Y; *Atomic weight*, 61·7 (Bahr and Bunsen); 71·4 (Delafontaine).—An element belonging to the class of earth-metals, but existing only in a few very rare minerals. Gadolin, in 1794, obtained from the ytterbite or gadolinite of Ytterby in Sweden, a peculiar oxide resembling lime and alumina. Ekeberg, in 1797, confirmed these results, and named the earth yttria. In a subsequent examination of this earth, which in the meantime had been investigated also by Klaproth and Vauquelin, Ekeberg found that his yttria contained glucina. Berzelius, in 1819, found that it also contained oxide of cerium (associated, according to subsequent investigations, with the oxides of lanthanum and didymium). Scheerer, in 1842, pointed out that yttria, even when freed from the oxides of the cerium-metals, probably still contained another oxide; and Mosander, in 1843, by a careful examination of crude yttria, concluded that it was a mixture of three earths—which he named yttria, terbia, and erbia—separable by their different degrees of basicity. Subsequent experiments by different chemists have, however, thrown considerable doubt on the separate existence of the second of these earths; and the recent very careful experiments of Bahr and Bunsen, already referred to under TERBIUM (p. 721), seem to have shown conclusively that crude yttria, when completely freed from the oxides of cerium, lanthanum, and didymium, may be separated into two earths, yttria and erbia, without any trace of a third, the so-called terbia. The method of effecting this separation, and obtaining pure salts of erbium and yttrium, has been already described (p. 721).

Metallic yttrium is obtained by igniting chloride of yttrium with potassium. It is described by Berzelius as a blackish-grey powder, consisting of small metallically lustrous scales, becoming brittle, and acquiring the colour and lustre of iron under the burnisher. The metal thus characterised was, however, a mixture of yttrium and erbium; pure yttrium has not yet been prepared.

Yttrium is a diatomic metal, and forms but one series of compounds, YCl^2, YO, &c. It unites directly at high temperatures with chlorine, oxygen, and sulphur, and probably with other metalloïds.

Bromide of Yttrium is obtained, by evaporating a solution of yttria in hydrobromic acid, as a very deliquescent saline mass.

Chloride of Yttrium is a non-volatile compound, obtained by heating yttrium in chlorine-gas.

The *hydrated chloride*, obtained by leaving a solution of yttrium in hydrochloric acid to evaporate, is a saline mass which slowly deliquesces.

Fluoride of Yttrium occurs, together with the fluorides of cerium and calcium, in varying proportions, as yttrocerite, a mineral found at Finnbo and Broddbo in Sweden; at Amity, New York, and in Massachusetts, forming violet-blue, crystallo-granular, and earthy masses, imbedded in quartz; in smaller quantity also as fluocerite (ii. 609). By mixing a solution of yttrium-chloride with potassium-fluoride, hydrated yttrium-fluoride is obtained as a white amorphous precipitate, having an astringent taste; it reddens litmus, is insoluble in water and in aqueous hydrofluoric acid; when heated in a close vessel, it leaves the anhydrous fluoride.

Borofluoride of Yttrium, obtained by double decomposition, is insoluble in water, but soluble in acids, even in excess of fluoboric acid, and crystallises on evaporating the solution.—The *silicofluoride* exhibits similar properties.

Iodide of Yttrium is prepared like the bromide, and is likewise very deliquescent.

Oxide of Yttrium,—Yttria,—obtained by igniting the oxalate, is a soft nearly white powder, which, when ignited, glows with a pure white light, and yields a spectrum not containing any bright bands, like that of erbia (p. 722). It does not unite directly with water, but is precipitated as a hydrate by alkalis from solutions of yttrium-salts. It dissolves slowly but completely in hydrochloric, nitric, and sulphuric acids, forming colourless solutions which do not exhibit an absorption-spectrum.

Oxygen-salts.—Basic Nitrate of Yttrium, $Y''(NO^3)^2.Y''O.3H^2O$, prepared like the corresponding erbium-salt (p. 722), crystallises in colourless deliquescent needles.—The *oxalate*, $C^2Y''O^4.H^2O$, is a soft white powder, which does not give off its water till heated nearly to the temperature at which it decomposes.—The *sulphate*, $3Y''SO^4.8H^2O$, forms colourless well-defined crystals, isomorphous with the corresponding erbium- and didymium-salts, and exhibiting the same characters as the erbium-salt when heated, and when dissolved in water. (Bahr and Bunsen.)

Selenide of Yttrium is obtained, according to Wöhler, by fusing yttria with selenium, as a black substance which is insoluble in water, and gives off selenhydric acid when treated with dilute acids (Wöhler). Selenide of ammonium precipitates yttrium-salts. (Berzelius.)

Sulphide of Yttrium is produced, with ignition, when yttrium is heated in sulphur-vapour; also when yttria is heated in vapour of carbonic disulphide. It is a grey pulverulent body, which is not decomposed by water, but gives off sulphydric acid when treated with dilute acids. (Wöhler.)

Detection and Estimation of Yttrium.

Yttrium-salts are colourless, and resemble those of thorinum (p. 786), in their behaviour before the blowpipe, and in most of their reactions in solution. Yttrium is distinguished from thorinum by the solubility of its ignited oxide in hydrochloric acid, by the non-volatility of its anhydrous chloride, and by the solubility of yttrio-potassic sulphate (precipitated from yttrium-solutions by potassic sulphate), in excess of potassic sulphate. The solubility of ignited yttria in hydrochloric acid serves also to distinguish yttria from alumina and zirconia; it is further distinguished from alumina and from glucina by its insolubility in potash. The precipitation of yttria by alkalis is not prevented by the presence of tartaric acid (distinction from alumina, glucina, thorina, and zirconia), the yttrium being slowly but completely precipitated as tartrate. Acidulated solutions of yttrium-salts do not alter the colour of turmeric-tincture (distinction from zirconium).

For quantitative estimation, yttrium is precipitated as hydrate by *ammonia* or *potash*, or as oxalate by *oxalic acid*; the precipitate in either case leaves anhydrous yttria when ignited. If potassium-salts are present in the solution, the precipitate formed by oxalic acid consists of yttrio-potassic oxalate, which, when ignited, leaves a mixture of yttria and potassic carbonate. This may be dissolved in hydrochloric acid, and the yttria precipitated by ammonia.

Yttrium may be separated from iron, existing in solution as ferric salt, by precipitating the iron as ferric oxide with *succinate of ammonium*, or (better) with *carbonate of barium*.—From the cerium-metals, yttrium is separated by immersing in the solution an excess of solid *sulphate of potassium*; the yttrio-potassic sulphate then dissolves, while the double sulphates of potassium and the cerium-metals remain undissolved.—From aluminium and glucinum, yttrium may be separated by precipitation with *oxalic acid*, or by adding *tartaric acid* in excess, and precipitating the yttrium with *ammonia*.—To separate yttrium from magnesium, the solution is mixed with excess of ammonium-salt, and the yttria precipitated by *ammonia*.

In all these modes of precipitation, yttrium is thrown down, together with erbium. The only satisfactory method yet given for separating these metals one from the other is that of Bahr and Bunsen, already described; and even this is very far from affording the means of determining the relative quantities of the two when mixed together.

The atomic weight of yttrium is determined by the analysis of its sulphate. From the anhydrous salt, $Y''SO^4$, or $YO.SO^3$, Bahr and Bunsen obtained, in two determinations, 49·30 and 49·24 per cent. YO, 50·69 and 50·76 per cent. SO^3: whence Y = 61·7. Delafontaine obtained, as a mean of three determinations, 48·23 per cent. OY, giving Y = 74·5.

YTTROCERITE. A mineral consisting of fluoride of yttrium mixed with the fluorides of cerium and calcium (p. 1064).

YTTROCOLUMBITE. Syn. with YTTROTANTALITE.

YTTROILMENITE. Uranoniobate of yttrium and iron: syn. with SAMARSKITE (iv. 54).

YTTROTANTALITE. Tantalate of yttrium, found at Ytterby in Sweden (p. 668).

YTTROTITANITE. *Keilhauite.*—A silicotitanate containg lime, yttria, ferric oxide, and alumina, with small quantities of other bases. It occurs at Buö, near Arendal in Norway, in monoclinic crystals, isomorphous with sphene (p. 398), more or less translucent, having a brownish-red to dark-brown colour, with yellowish streak; waxy lustre on the neutral faces, vitreous on the cleavage-faces. Hardness = 6 to 7; specific gravity = 3·5 to 3·7. Before the blowpipe it behaves, for the most part, like sphene.

Analyses: *a*, *b*, by A. Erdmann (Berz. Jahresb. xxv. 328).—*c*, by D. Forbes (Ed. N. Phil. J. [new series], i. 62).—*d*, *e*, by Rammelsberg (Pogg. Ann. civ. 296):

	SiO^2.	TiO^2.	Fe^2O^3.	Al^2O^3.	YO.	CeO.	CaO.	MnO.		Loss by ignition.	
a. . .	30·00	29·01	6·35	6·09	9·62	0·32	18·92	0·67	. .	. .	= 100·98.
b. . .	29·45	28·14	6·48	5·90	9·74	0·63	18·68	0·86	. .	. .	= 99·88.
c. . .	31·33	28·84	7·63	8·23	4·78	0·28	19·56	. .	0·32 GO	. .	= 100·97.
d. (cryst.)	29·48	26·67	6·75	5·45	8·16	. .	20·29	. .	0·94 MgO 0·60 K^2O	0·54	= 98·88.
e. (massive)	28·50	27·04	5·90	6·24	12·08	. .	17·15	3·59	. .	. .	= 100·50.

If the ferric oxide and alumina be regarded as acid constituents, the mineral may be represented by the formula $3M''O(Al^2O^3;Fe^2O^3) + 15M^2O.2(SiO^2;TiO^2)$, analogous to that of sphene. (Rammelsberg.)

YU. The name of a mineral highly prized in China, and, according to Abel-Remusat (Berz. Jahresb. v. 223), identical with *jade nephritique* (? nephrite). It has a specific gravity of 2·9 to 3·4, scratches glass, and is scratched by quartz.

Z

ZACOTINGA. A specular iron-ore from Porpez, in Brazil.

ZAFFRE. An impure oxide of cobalt, produced by imperfectly roasting cobalt-ore mixed with 2 or 3 pts. of siliceous sand.

ZALA. Syn. with BORAX.

ZAMBONI'S PILE. A name sometimes applied to the dry pile. (See ELECTRICITY, ii. 423.)

ZAMTITE. A hydrated carbonate of nickel from Spain, probably identical with texasite or emerald-nickel (i. 789).

ZANTHOPICRIN. Syn with XANTHOPICRITE (p. 1053).

ZEAGONITE. A calcio-aluminic silicate allied to abrazite (i. 1), but crystallising in trimetric forms, whereas abrazite is dimetric. It occurs in the lava of Capo di Bove, near Rome, in small crystals, which are combinations of the prisms $\infty\breve{P}\infty$ and $\infty\bar{P}\infty$, with a pyramid, or in irregular and spherical groups. It is transparent to semitranslucent, with a vitreous lustre, white to bluish-white colour, and white streak. Hardness = 5·0. Specific gravity = 2·213. Before the blowpipe it becomes opaque, then splits, and melts to a transparent or whitish tumefied glass. Hydrochloric acid dissolves it, with separation of gelatinous silica.

Analyses: *a*, by v. Kobell (J. pr. Chem. xviii. 205);—*b*, by Marignac (Ann. Ch. Phys. [3], xiv. 41):

	SiO^2.	Al^2O^3.	CaO.	K^2O.	H^2O.		
a.	42·72	25·77	7·60	6·28	17·66	=	100·03
b.	43·64	24·39	6·92	10·35	15·05	=	100·35

These analyses do not agree very closely, but the formula of the mineral is probably that deduced from the second, viz. $(CaO;K^2O)SiO^2 + (Al^2O^3.2SiO^2) + 4aq$.

ZEASITE. A dark-coloured opal from Mexico, exhibiting a green and red play of colours.

ZEDOARIN. See the next article.

ZEDOARY. *Radix zedoariæ.*—The root of *Curcuma zedoaria*, a scitaminaceous plant, growing in Bengal, Java, and Madagascar. It has a camphoric odour, and an aromatic somewhat bitter taste. Contains, according to Bucholz (Repert. Pharm. xx. 376), volatile oil, a bitter soft resin, a bitter extractive matter, gum, starch, &c. The oil is turbid, whitish-yellow, and viscid, has a camphoric taste and smell, and consists of two oils, one lighter, the other heavier, than water. Trommsdorff obtained from the root a substance which he called zedoarin, but did not further describe.

ZEILANITE. Syn. with PLEONAST or FERRUGINOUS SPINEL (p. 400).

ZEIODELITE. This name is applied to a mixture obtained by stirring 24 pts. of finely-pounded glass into 20 pts. of sulphur. It is recommended as a cement for stone and metal, for the taking of casts instead of gypsum or sulphur; as a material for bookbinding letters, stereotype plates, statues, and whetstones; and even as a substitute for lead in the construction of vitriol chambers. It may be tinted at pleasure, by addition of colouring-matter. (A. Vogel, Buch. N. Repert. xii. 294.)

ZEA MAÏS. Maize or Indian-corn. On the composition of the grain of this plant, see CEREALS (i. 225, 227).

ZEIN. A nitrogenous substance obtained from maize-flour (Gorham, Berz. Jahresb. ii. 124.—Stepf, J. pr. Chem. lxxvi. 88; Jahresb. 1859, p. 593).—Maize-flour, when washed with water, does not yield a mass resembling the gluten of wheat.

ZEOLITES. A generic name of hydrated double silicates in which the principal bases are alumina and lime, the latter being often more or less displaced by ferrous oxide, magnesia, and alkalis. They boil up when heated on charcoal before the blowpipe, and are dissolved by acids, leaving gelatinous silica. Many of them form very fine crystals. Natrolite is sometimes called *feather zeolite*; stilbite, *foliated zeolite*; scolecite, *needle zeolite*; apophyllite, *pyramidal zeolite*; laumontite, *efflorescing zeolite.*

ZEOTIN-SALT. Syn. with NITRATE OF SODIUM (iv. 105).

ZER [illegible] **T** This name appears to be applied to two different roots—

namely, that of *Zingiber Cassumanar*, a scitaminaceous plant indigenous in Coromandel and in Java; and that of *Zingiber Zerumbet*, imported from Calcutta and Java. Both have an aromatic odour and a bitter taste. According to Luca (Berl. Jahrb. 1798, iv. 214), zerumbet-root (the particular kind is not stated) contains an essential oil having a camphoric odour, a bitter and soapy extractive matter, bitter resin, gum, &c.

ZINC. Synonyms: *Spelter. Spiauter. Zincum.* Atomic weight, 65; Symbol, Zn.—The ore of zinc, called calamine or cadmia,—but not the pure metal—was known to the ancient Greeks, and used in the manufacture of brass. Metallic zinc was first mentioned by Paracelsus; it was for a long time imported from the East, but since the middle of the eighteenth century, it has been prepared in Europe.

Zinc occurs in considerable abundance as carbonate, forming the ore called calamine; as silicate, or siliceous calamine; as sulphide or blende, and as oxide or red zinc-ore; in smaller quantities also as aluminate, arsenate, phosphate, and sulphate. Quite recently, native metallic zinc has been found at Victoria, in Australia. Zinc is likewise found in the ash of a species of violet, *Viola calaminaria*, which grows on the dead heaps at the calamine mines in Rhenish Prussia.

Metallurgy of Zinc.—The ores from which the metallic zinc of commerce is extracted are four in number—viz., blende, red oxide, calamine, and siliceous calamine. All these are subjected to a preliminary calcination before being smelted.

In the case of blende, this calcination is necessary for the purpose of expelling the sulphur, and converting the sulphide into a more or less pure oxide of zinc. The calamine, on calcination, loses its carbonic acid, together with some moisture; and the red oxide and siliceous calamine, besides losing water, become more porous and disintegrated, whereby their subsequent reduction is facilitated.

Calamine was formerly roasted in kilns, but is now generally calcined in reverberating furnaces. Zincblende is occasionally submitted to a preliminary roasting in kilns, so as to utilise the sulphurous acid which is evolved; but in all cases it requires to be ground, and the calcination completed in reverberatory calciners, similar to those used in copper-smelting.

Reduction.—The roasted ore is mixed with half its weight of powdered charcoal, coke, or anthracite, and introduced into crucibles or retorts of peculiar construction. In Silesia, whence the greater part of the zinc used in the arts is obtained, the mixture of zinc-oxide and charcoal or coke is heated in muffles 3 feet long and 1½ foot high, six of which (three side by side) are laid in one furnace. The evolved mixture of carbonic oxide gas and zinc-vapour passes from the upper and fore part of the muffles, through a knee-shaped channel, horizontal in the nearer and directed downwards in the farther part, and the zinc condenses therein, and drops down from its lower aperture. Part of the zinc-vapour, and likewise some cadmium-vapour, escapes uncondensed, together with the carbonic oxide gas, and burns in the air, producing the substance called *Silesian Zinc-flowers*. In Liège, the reduction is performed in earthernware tubes, laid side by side. The zinc, as it condenses in the fore part of these tubes, is scraped out from time to time in the liquid state. In England, a number of cast-iron pots are arranged in a circle in one common furnace. Through the bottom of each of these pots there passes a tube, open at both ends. The vessels are filled with the mixture to such a height as not to stop up the upper end of the tube, then closed with a well-fitting cover, and heated. The zinc drops down from the part of the tube which descends from the bottom of the crucible. This process is called *Destillatio per descensum.*—At Goslar, in the Harz, zinc is obtained as a secondary product in the smelting of lead-ores. The zinc-vapours condense in the upper half of the furnace, and run down from the shaft upon a slanting stone called the *zinc-stool*. The zinc thus obtained is melted in iron pots, and poured out on tables.*

Purification.—Commercial zinc contains small quantities of lead and iron, together with minute quantities of tin and cadmium, and occasionally traces of arsenic and copper. Carbon is also mentioned amongst its impurities; but Eliot and Storer did not find it in either of the thirteen specimens which they examined, though traces of sulphur were always present. The best mode of obtaining pure zinc is to pass sulphuretted hydrogen through a strong and somewhat acid solution of zinc-sulphate, filtering from any precipitate that may be formed, and, after boiling the solution to expel the sulphuretted hydrogen, precipitating the zinc as carbonate by addition of sodium-carbonate. The carbonate, after being washed, is redissolved in pure sulphuric acid, and the zinc is reduced by electrolysis; or the dried carbonate may be converted into oxide by ignition, and the oxide distilled in a porcelain retort, with charcoal prepared from loaf-sugar.

---

* For details and figures, see *Ure's Dictionary of Arts, &c.* iii. 1072, and Miller's *Elements of Chemistry*, 3rd ed., part ii. p. 540.

Properties.—Zinc is a white metal, with a shade of blue, capable of being polished, and then assuming a bright metallic lustre. It is usually brittle, and its fracture exhibits a crystalline structure. But zinc, if pure, may be hammered into thin leaves, at the usual temperature; and commercial zinc, which is impure and brittle at a low temperature, acquires the same malleability between 100° and 150°: it may then be laminated; and the metal is now consumed, in the form of sheet-zinc, for a variety of useful purposes. At 210° it again becomes brittle, and may be reduced to powder in a mortar of that temperature. The density of cast zinc is 6·862, but it may be increased by forging to 7·21. It melts at 412° (Daniell), and boils at 1040° (Deville and Troost). At a red heat, zinc rises in vapour, and takes fire in the air, burning with a white flame like that of phosphorus; the white oxide produced is carried up mechanically in the air, although itself a fixed substance. Laminated zinc is a valuable substance, from its slight disposition to undergo oxidation. When exposed to air, or placed in water, its surface becomes covered with a grey film of suboxide, which does not increase; this film is better calculated to resist both the mechanical and chemical effects of other bodies than the metal itself, and preserves it. Ordinary zinc dissolves with facility in dilute *hydrochloric*, *sulphuric* and other *hydrated acids*, by substitution for hydrogen. Pure zinc dissolves very slowly in the same acids, unless it is in contact with platinum, copper, or any other less positive metal, with which it can form a galvanic circuit. Ordinary zinc dissolves more quickly than the pure metal, because the lead contained in it is precipitated in the metallic state, and acts as an electronegative element to the zinc (see Electricity, ii. 420). In consequence of this electrolytic action, zinc, in contact with iron or copper in a saline solution, protects the other metal from oxidation.—*Galvanised iron* consists of iron having its surface coated with zinc, which, in like manner, protects it from oxidation in air and water. Zinc precipitates silver, copper, mercury, and most of the basylous metals, less oxidable than itself, from their acid solutions.

Zinc dissolves also in aqueous alkalis, with evolution of hydrogen, forming a zincate of the alkali-metal: *e.g.*, $Zn + 2KHO = K^2Zn''O^2 + H^2$. In this case, also, the solution of the zinc is accelerated by contact with less oxidable metals, as platinum, iron, &c.

Zinc reduces many metallic *oxides* (chromic oxide, for example) when melted with them. Nearly all *chlorides* and *fluorides* are reduced when heated with zinc-vapour in an atmosphere of hydrogen (Poumarède, J. pr. Chem. lxxiii. 496). At a very high temperature, zinc reduces *carbonic anhydride*, forming *oxide of zinc*; at a somewhat lower temperature, on the contrary, charcoal reduces oxide of zinc (p. 1067).

Zinc is a diatomic metal, and forms, for the most part, but one class of compounds: $ZnCl^2$, ZnO, $Zn(NO^3)^2$, $ZnSO^4$, &c. A lower and a higher oxide are known, but they are not of very definite character.

ZINC, ALLOYS OF. Zinc unites with nearly all other metals, forming alloys which are mostly hard, and in some cases brittle. They may be prepared by directly fusing the two metals together; if, however, the heat be allowed to rise too high, the zinc will be volatilised. Most of the zinc-alloys have been already described in connection with other metals.

Zinc does not form an alloy with bismuth; on mixing the two metals in the melted state, the mass separates into two layers—one consisting of zinc containing 2·4 per cent. bismuth, the other of bismuth containing from 8·6 to 14·3 per cent. zinc. (Matthiessen and v. Bose.)

Tin unites readily with zinc by fusion, forming alloys which are harder than tin, but softer than zinc; they are also less malleable than tin. An alloy of 11 pts. tin to 1 pt. zinc beaten out into leaf, forms spurious silver-leaf. According to Rudberg, the alloy $ZnSn^6$ (1 pt. tin to 10¾ pts. zinc) solidifies completely at 204°; but all the other alloys separate on cooling from a state of fusion into two portions, the one consisting of $ZnSn^6$, not solidifying till cooled to 204°, while the remainder, consisting of an alloy containing a larger proportion of one or the other metal, solidifies at a higher temperature: thus—

	$Sn^{12}Zn$.	Sn^6Zn.	Sn^4Zn.	Sn^3Zn.	Sn^2Zn.	$SnZn$.
Variable point . . .	210°	. .	230°	250°	280°	320°.
Fixed point . . .	204°	204°	204°	204°	204°	204°.

Respecting the alloys of zinc, tin, and lead, see Lead (iii. 538).

Alloys of zinc, tin, and copper constitute many varieties of bronze, tombac, &c. Alloys containing smaller proportions of zinc are used, on account of their hardness, to form the journals and other parts of machines. (See Copper, Alloys of, ii. 461.)

According to Calvert and Johnson, the alloys $ZnCu^{10}Sn$ and $ZnCu^{18}Sn$ are definite chemical compounds, inasmuch as they are scarcely attacked by nitric acid of specific gravity 1·1, or by concentrated hydrochloric acid, and not at all by sulphuric acid, of specific gravity 1·6. Both these alloys, on account of their hardness, are well adapted to form parts of machinery.

Some bronzes contain lead as well as copper, tin, and zinc: thus, *British bell-metal* consists of 5·6 pts. zinc, 10·1 tin, 80·0 copper, and 4·3 lead; and the *biddery-ware* of India, of 3 pts. of an alloy of copper, tin, and lead (16 pts. copper to 4 pts. lead and 2 pts. tin), to 16 pts. zinc. (Williams.)

An *amalgam* of zinc and tin is used for coating the rubbers of electrical machines.

ZINC, BROMIDE OF. $ZnBr^2$.—This compound is formed directly by igniting zinc in bromine-vapour. A solution of zinc or zinc-oxide in aqueous hydrobromic acid solidifies, at a certain degree of concentration, to an indistinctly crystalline, very deliquescent mass of the hydrated bromide mixed with a certain quantity of oxide, which, when heated, yields a sublimate of zinc-bromide in white needles of specific gravity 3·643, and a residue of zinc-oxide. According to Kremers (Pogg. Ann. ciii. 57; civ. 133; cviii. 115), solutions of zinc-bromide of different strengths exhibit, at 19·5°, the specific gravities shown in the following table:—

Quantity of $ZnBr^2$ in 100 pts. water .	20·6	42·6	76·0	91·4	111·2	150·3	213·0	318·3
Specific gravity at 19·5° .	1·1715	1·3770	1·5276	1·6101	1·7082	1·8797	2·1027	2·3914

A solution of zinc-bromide in ammonia yields, by evaporation, colourless octahedrons of zinc-ammonium-bromide, $(N^2H^6Zn'')Br^2$, which are decomposed by heat and by water. (Rammelsberg.)

By the simultaneous action of zinc and bromine on anhydrous ether, there is formed, together with bromide of carbon, an unstable compound of ether and zinc-bromide, which fumes in the air and dissolves in water. (Nicklès, Compt. rend. lii. 870.)

Zinc-bromide unites with the bromides of alkali-metals, forming double salts, exactly like the corresponding chlorine-compounds. The ammonium-salt has a specific gravity of 2·628. (Bödecker.)

ZINC, CHLORIDE OF. $ZnCl^2$. *Butter of Zinc. Butyrum Zinci.*—Very thin zinc-foil takes fire at ordinary temperatures in chlorine-gas. Zinc-chloride is formed in the wet way by dissolving zinc or zinc-oxide in hydrochloric acid, or by decomposing certain metallic chlorides in solution with zinc or a zinc-salt: thus, when a solution containing equivalent quantities of zinc-sulphate and sodium-chloride is cooled, zinco-sodic sulphate crystallises out at + 10°; but at 0°, pure sodic sulphate separates, while zinc-chloride remains in solution.—Anhydrous zinc-chloride may be prepared by distilling 1 pt. of zinc-filings with 2 pts. of mercuric chloride, or 1 pt. zinc-oxide with 2 pts. sal-ammoniac, or by distilling the residue left on evaporating the aqueous solution; also by distilling a mixture of dry zinc-sulphate and calcium-chloride.

Zinc-chloride is a whitish-grey translucent substance, soft like wax, and of specific gravity 2·753; it has a burning taste and emetic action; melts easily, and distils or sublimes in white needles at a red heat; deliquesces quickly on exposure to the air, and dissolves easily in water and in alcohol.

The aqueous solution evaporated to a syrup, with addition of a little hydrochloric acid, deposits a hydrated salt, $ZnCl^2.H^2O$, in small deliquescent octahedrons. The specific gravities of solutions of various strengths are, according to Kremers, as follows:

Quantity of $ZnCl^2$ in 100 pts. water .	16·7	38·8	56·3	92·4
Specific gravity at 19·5° . . .	1·331	1·2714	1·3677	1·5336

A saturated alcoholic solution of zinc-chloride deposits an alcoholate, $ZnCl^2.C^2H^6O$, in small crystals. (Graham.)

Anhydrous zinc-chloride is a powerful dehydrating agent, acting upon organic bodies like oil of vitriol; thus it chars wood, converts alcohol into ether, and has been recommended by Kraft and Mottay (Compt. rend. xlviii. 410), instead of sulphuric acid, for the preparation of fatty acids from glycerides. Even the concentrated aqueous solution destroys vegetable fibre, and cannot therefore be filtered through paper; according to Persoz, it dissolves silk.

A dilute aqueous solution of zinc-chloride is much used, under the name of *Burnett's Disinfecting Fluid*, as an antiseptic, and for preserving wood and vegetable fibre against decay. The concentrated solution is used in the laboratory as a bath for heating substances to a constant temperature. The dry chloride, obtained by evaporation, is used in surgery as a caustic.

Zinc-chloride combines easily with *ammonia*, with *chlorides of alkali-metal*, and with *zinc-oxide*, forming several oxychlorides.

a. With Ammonia.—When a hot concentrated solution of zinc-chloride is treated with gaseous or aqueous ammonia, till the resulting precipitate redissolves, the solution, on cooling, deposits the compound $4NH^3.ZnCl^2.H^2O$, in shining scales or laminæ, which, when heated to 150°, give off water and ammonia, and leave zinc ammonium-

chloride, $2NH^3.ZnCl^2 = (N^2H^6Zn'')Cl^2$, in the form of
pound separates also, in shining rhombic crystals, fro
solution of zinc-chloride—sometimes immediately, so
of the diammoniacal compound. Both the precedin
heated, give off ammonia, and leave a clear liquid, wh

(Sorel.)

ZINC, CYANIDE OF. See CYANIDES (ii. 274).

ZINC, DETECTION AND ESTIMATION
tions.—All zinc-compounds, when heated with *sodium*
give an incrustation of zinc-oxide, which is yellow while
ing; it is not volatile in the outer flame. With *borax*,
either flame a bead, which is yellowish while hot, white
zinc-salt is present. If the colourless bead or the
with a dilute solution of *cobalt-nitrate*, and strongly he
green colour is produced.

2. *Reactions in Solution.*—Zinc-salts are colourless, and form colourless solutions.—*Sulphydric acid* gives, with neutral solutions of zinc-salts, a white precipitate of zinc-sulphide, which does not contain all the zinc; in solutions containing a sufficient quantity of free hydrochloric or sulphuric acid, no precipitate is formed; but from acetate of zinc, or any zinc-salt mixed with acetate of sodium, zinc is completely precipitated by sulphydric acid, even if a large quantity of free acetic acid is present. Sulphide of zinc is insoluble in caustic alkalis.—*Sulphide of ammonium* precipitates zinc-salts completely.—*Cyanide of potassium* throws down white cyanide of zinc, soluble in excess, and reprecipitated by sulphide of ammonium.—*Ferrocyanide of potassium* forms a white precipitate, insoluble in hydrochloric acid.—*Oxalic acid* and *phosphate of sodium* precipitate white oxalate and phosphate of zinc, soluble in acids and alkalis; the phosphate is not precipitated in presence of sal-ammoniac and ammonia.—*Fixed alkaline carbonates* precipitate a white basic carbonate, insoluble in excess, soluble in alkalis; chloride of ammonium hinders this precipitation in the cold.—*Potash, ammonia*, and *carbonate of ammonium* form white precipitates soluble in excess, reprecipitated on diluting with water and on boiling; soluble also in chloride of ammonium. Sulphydric acid precipitates zinc-sulphide from these solutions.

Zinc in solution is distinguished from all other metals by the precipitation of its white sulphide by sulphide of ammonium, in a solution containing excess of caustic alkali.

3. *Estimation and Separation.*—Zinc is precipitated from its solutions by *carbonate of sodium*, which, when added in excess, and boiled with the solution, throws down carbonate of zinc. It is best, however, to pour the zinc-solution into the hot solution of the alkaline carbonate, because, in that case, we may be sure of not forming a basic salt. If the zinc-solution contains ammoniacal salts, it must be boiled with a quantity of carbonate of sodium sufficient to decompose those salts, then evaporated to dryness, the residue treated with a large quantity of water to dissolve out the soluble salts, and the carbonate of zinc collected on a filter, and well washed with hot water. The evaporation should be conducted as quickly as possible. The carbonate of zinc, when dried and ignited, yields oxide of zinc containing 80·26 per cent. of the metal.

In separating zinc from other metals, it is often necessary to precipitate by *sulphide of ammonium*. If the solution is acid, it must be previously neutralised by ammonia. The precipitate must not be thrown on the filter immediately, but left to settle down completely, after which the clear liquid must first be passed through the filter, and then the precipitate thrown on it. If this precaution be neglected, the sulphide of zinc will stop up the pores of the filter. The precipitate is washed with water containing a little sulphide of ammonium; then dissolved in hydrochloric acid; the solution boiled to drive off the sulphydric acid; and the zinc precipitated by carbonate of sodium as above.

Zinc is separated from all the non-metallic elements, and from the metals of alkalis and alkaline-earths (barium, strontium, and calcium), by *sulphide of ammonium*. In the case of the alkaline earths, however, great care must be taken to prevent the ammoniacal liquid from absorbing carbonic acid from the air, as that would occasion a precipitation of the earth-metal in the form of carbonate. For this purpose, the filtration must be effected as quickly as possible, and the liquid well protected from the air. The separation of zinc from barium may also be effected by *sulphuric acid*, and from calcium by *oxalate of ammonium*.

From magnesium, zinc may be separated by *sulphide of ammonium*, a sufficient quantity of chloride of ammonium being previously added, to prevent the precipitation of the magnesia; or the separation may be effected by converting the zinc and magnesium into acetates, and precipitating the zinc as sulphide by *sulphydric acid*.

The separation of zinc from aluminium, glucinum, and chromium (in the form of chromic oxide) may also be effected by converting the bases into acetates, and precipitating the zinc with *sulphydric acid*, or by dissolving in potash, and precipitating the zinc with sulphydric acid; but the first method is to be preferred. Chromium, in the form of chromic acid, is separated from zinc, as from other metals, by fusion with an *alkaline carbonate* (i. 145).

The conversion into acetates, and precipitation by sulphydric acid, likewise serves to separate zinc from zirconium, yttrium, thorinum, and manganese. The separation from manganese may also be effected by converting the two metals into chlorides, passing *chlorine-gas* through the solution to convert the manganese into dioxide, and completing the precipitation of the latter with *carbonate of barium*.

From iron, zinc may be separated by *ammonia*, or (better) by *succinate of ammonium* (iii. 386). The iron (in the state of ferric oxide) may also be precipitated by *carbonate of calcium* or *barium*.

Uranium, as uranic oxide, may be separated from zinc by this latter mode of precipitation.

For the methods of separating zinc from cobalt (i. 1047; iv. 39).

From molybdenum, tungsten, and vanadium, insolubility of its sulphide in sulphide of ammonium. it from titanium, see p. 839.—From thallium, zinc the thallium with *iodide of potassium* (p. 749).

From arsenic, antimony, copper, and all other soluble in acids, zinc is separated by precipitating thos in solutions containing excess of mineral acid.

4. *Atomic Weight of Zinc.*—Gay-Lussac (Mé dising zinc with nitric acid, and by measuring the quant zinc dissolves in dilute acids, concluded that 100 pts. pts. oxygen: whence Zn = 64·56.—Berzelius (Gilb. An first method, nearly the same number.—Jacquelain by the decomposition of the nitrate and sulphate of zinc ing with the number 66·24; and Favre's experime composition of zinc-oxalate, and on the quantity of hy solves in hydrochloric acid, give the number 66·0 for th sequently (in 1844), A. Erdmann (Ann. Ch. Pharm. of zinc, mixed it with pure charcoal obtained from suga of hydrogen; he then oxidised the metal with nitric aci by ignition. The atomic weight of zinc, calculated from thus conducted, is 65·04. The same number was obtain of zinc-lactate.

ZINC, FLUORIDE OF. ZnF^2.—Zinc dissolves and the solution, when evaporated, deposits the hydrat shining, rhombic octahedrons, exhibiting the combinati Zinc-fluoride dissolves slowly but completely in water, mo fluoric, hydrochloric, or nitric acid, or of ammonia. W it dissolves oxide of zinc.

Zinc-fluoride forms double salts with the fluorides —The *aluminium-salt*, $ZnF^2.Al^2F^6$, forms long colourle $2KF.ZnF^2$, colourless crystalline grains.

ZINC, HYDRATE OF. See ZINC, OXIDE OF (p.

ZINC, IODIDE OF. ZnI^2.—Finely-divided zin forming an easily fusible compound, which sublimes 4·696. The same compound separates in regular octahe evaporating a solution obtained by digesting iodine wit the colour of the iodine disappears.

Zinc-iodide is very deliquescent, and dissolves easily i of the solution varies with its strength, in the manner (Kremers):—

Quantity of ZnI^2 in 100 pts. water .	21·5	30·0	46·4	74·4
Specific gravity at 19·5°	1·1715	1·2340	1·3486	1·5121

Zinc-iodide is decomposed when heated in contact wit and zinc-oxide produced.

The aqueous solution dissolves zinc in contact with th deposits an oxyiodide on cooling (Müller, J. pr. solution, digested with iodine, forms a brown liquid zinc.

Dry zinc-iodide absorbs 27 per cent. (nearly 6 at.) loose white powder, soluble in acids but decomposed b iodide in aqueous ammonia deposits, by spontaneous ev prisms of the compound $4NH^3.ZnI^2$, which is also deco

Zinc-iodide unites with iodides of alkali-metals, double salts, which may be crystallised by evaporation $2NH^4I.ZnI^2$, $KI.ZnI^2$, $NaI.ZnI^2.\frac{3}{2}H^2O$, and $BaI^2.2ZnI$

ZINC, NITRIDE OF. This compound is form electrolysis of water containing sal-ammoniac, when t zinc and the negative pole of platinum.

ZINC, OXIDES OF. Only one oxide of zinc is protoxide. The grey film, which forms on the surface of regarded by Berzelius as a suboxide; but it is proba oxide with metallic zinc. Thénard also states that a gelatinous peroxide is produced by the action of hydric peroxide on hydrated zinc-oxide.

Zinc-oxide, ZnO.—This oxide occurs native, contaminated with manganese-oxides, as zincite or red zinc-ore, and combined with the sesquioxides of manganese and iron, as franklinite, both of which minerals are found at Sterling Hill, Sussex County, New Jersey—the former in hexagonal, the latter in monometric forms. It is formed by the combustion of zinc in the air, and by ignition of zinc-salts containing volatile acids; frequently also in the smelting of metallic ores containing zinc, and is occasionally deposited in furnace-flues in six-sided prisms. Crystallised zinc-oxide is also produced by heating zinc-chloride in a current of aqueous vapour.

The ordinary amorphous oxide is obtained, as a fine flocculent powder, by burning zinc in contact with the air. When zinc is thrown, by small quantities at a time, into a capacious earthen crucible previously heated to whiteness, it burns with a bright bluish-white flame, and deposits large flakes of the oxide mixed with small particles of the metal mechanically carried over: from these the oxide may be freed by levigation with water, the heavier metallic particles then subsiding, and leaving the pure oxide in suspension. This oxide is much used as a pigment, called zinc-white, and is manufactured for this purpose by distilling zinc from clay-retorts into chambers through which a current of air is kept up. The volatilised metal burns at the high temperature to which it is exposed under these circumstances, and the oxide is deposited in a series of condensing-chambers. The white pigment thus obtained is permanent, not being blackened, like white lead, by exposure to sulphuretted hydrogen; it is also much less poisonous than white lead. An impure oxide, sold under the name of tutty, is obtained from the flues of furnaces in which brass is melted.—For pharmaceutical purposes, zinc-oxide is prepared by igniting the precipitated hydrate or carbonate.

Zinc-oxide, when crystallised, forms transparent, yellowish, six-sided prisms of about 6·0 specific gravity. The ordinary oxide is a white amorphous powder, of about 5·6 specific gravity. It is insoluble in water. When heated it assumes a lemon-yellow colour, but becomes white again on cooling. It is very refractory in the fire, but is said to volatilise at the strongest white heat. It is easily reduced by charcoal, less easily by hydrogen or carbonic oxide. When heated with sulphur, it forms zinc-sulphide and sulphurous anhydride; with chlorine, at a red heat, it yields zinc-chloride, which distils over, and free oxygen.

Zinc-oxide is a strong base, dissolving completely in acids, and forming the zinc-salts. It also acts as a base towards oxides of the form M^2O^3; thus with alumina it forms gahnite, $ZnO.Al^2O^3$.—A solution of zinc-oxide in potash deposits, on addition of chromic hydrate, a green compound containing $ZnO.Cr^2O^3$ (Chancel).—Ebelmen (Ann. Ch. Phys. [3], xxxiii. 34) obtained such compounds (spinels) crystallised, by heating the component oxides with boric oxide for a long time in a pottery-furnace, till the boric oxide was volatilised.—The compound $ZnO.Cr^2O^3$ formed small blackish-green octahedrons, of specific gravity 5·309; $ZnO.Fe^2O^3$, microscopic, shining, black octahedrons, of specific gravity 5·132; $ZnO.Al^2O^3$ (gahnite), colourless octahedrons, harder than quartz, and having a specific gravity of 4·58.

Hydrated Zinc-oxide, or *Zinc-hydrate.*—Anhydrous zinc-oxide does not unite directly with water. Zinc-salts treated with ammonia yield a white gelatinous zinc-hydrate, soluble in excess of potash or ammonia. A crystallised monohydrate, $ZnO.H^2O = Zn''H^2O^2$, is obtained by immersing zinc in aqueous ammonia in contact with iron (Runge; Schindler), or with lead or copper (Nicklès). Hydrogen is then evolved, and after some time zinc-hydrate is deposited on the zinc in rhombic prisms, of specific gravity 2·677 (see also Cornu, Bull. Soc. Chim. 1863, p. 64).—A dihydrate, $ZnO.2H^2O = Zn''H^4O^3$, is deposited from a saturated solution of zinc-oxide in soda-ley, left to itself for a long time in a closed vessel. It forms colourless regular octahedrons, having a strong adamantine lustre, retaining their lustre and transparency after washing with water and drying over chloride of calcium, but becoming white when hot water is poured upon them. Zinc-hydrate dissolves readily in dilute acids, caustic alkalis, and carbonate of ammonium. It easily gives off its water when heated.

ZINC, PEROXIDE OF. (See p. 1070.)

ZINC, PHOSPHIDES OF. (Hoos, Ann. Ch. Pharm. c. 101.)—The compound Zn^3P^2 was obtained by strongly igniting 2 at. zinc-oxide with 1 at. phosphoric anhydride and 7 at. charcoal, and collected in the neck of the retort as a brittle sublimate, which had a dark steel-grey colour, and dissolved in hydrochloric acid, with evolution of non-spontaneously inflammable phosphoretted hydrogen.—Zinc-oxide, ignited in phosphorus-vapour, forms a black crystalline mass, together with a red phosphide of zinc. The black mass boiled with hydrochloric acid, left a grey crystalline powder, probably consisting of ZnP^2.

ZINC, SELENIDE OF. Formed by passing selenium-vapour over red-hot zinc. It is a lemon-yellow pulverulent body, from which nitric acid dissolves the zinc, and at first separates the selenium, but on prolonged action dissolves it as selenious acid. (Berzelius.)

ZINC, SELENIOCYANATE OF. See SELENIOCYANATES (p. 220).

ZINC, SILICOFLUORIDE OF. See SILICOFLUORIDES (p. 273).

ZINC, SUBOXIDE OF. (See p. 1072.)

ZINC, SULPHIDES OF. Of these compounds, the best known is that which corresponds to the oxide. According to Schiff, there is also a pentasulphide, ZnS^5.

The *protosulphide*, ZnS, occurs native as blende, in monometric forms, viz. ∞O (*fig.* 178, CRYSTALLOGRAPHY, ii. 124); $\pm \frac{O}{2}$ (*fig.* 189); the same with the two tetrahedrons equally developed, forming a regular octahedron (*fig.* 172); and $\frac{O}{2} \cdot \infty O$ (*fig.* 203); also twins like *fig.* 319 (ii. 160), and others; cleavage perfect parallel to ∞O. The mineral likewise occurs in botryoïdal and other imitative shapes, and massive, compact. Hardness = 3·5 to 4. Specific gravity = 3·9 to 4·2. Transparent to translucent. Lustre resinous to adamantine. Colour brown, yellow, black, red, green, white, or yellow when pure. Streak white to reddish-brown. Fracture conchoïdal. Brittle.

Analyses.—*a.* Franklin, New Jersey: colourless, transparent (Henry).*—*b.* Claussthal: crystallised, black (Kuhlemann).—*c.* Raibl, Carinthia: scaly (Kersten).—*d.* Przibram, Bohemia: radiate (Löwe).—*e.* Eaton, New Hampshire (Jackson).—. Shelburne, New Hampshire (Jackson).—*g.* Christiania: black-brown, radiate (Scheerer).—*h.* Marmato, near Popayan, South America: *marmatite*: black (Boussingault).—*i.* Bottino, near Serravezza, Tuscany: massive (Bechi):

Antimony	. . .	0·63	0·80 †						
	99·68	101·16	99·16						

Blende occurs in both crystalline and sedimentary rocks, and is usually associated with galena; also with heavy spar, copper-pyrites, spathic iron, and frequently in silver-mines. Derbyshire, Cumberland, and Cornwall afford the black varieties called *black jack*; also Transylvania, Hungary, and the Harz. Sala in Sweden, Ratieborzitz in Bohemia, and many Saxon localities, afford splendid black and brown crystals.

Zinc-sulphide cannot be formed by fusing sulphur and zinc together, because the sulphur volatilises before combination can take place; but it is produced, with detonation, when zinc-filings are heated with cinnabar or potassium-sulphide. It is likewise obtained by heating zinc-oxide with sulphur alone, or with sulphur and charcoal; by heating zinc-oxide or the hydrated sulphide in a stream of sulphydric acid gas; and, finally, by reducing zinc-sulphate with sulphur or charcoal. When prepared by either of these methods, it is a white or yellowish powder, of specific gravity 3·92: it melts at a very high temperature, and volatilises only at a white heat.

Crystallised zinc-sulphide is easily oxidised by fusion with nitre; slowly, but completely, when heated in contact with the air: acids decompose it slowly, with evolution of sulphydric acid. The amorphous sulphide is decomposed by atmospheric oxidation, or by acids, more quickly than the crystallised sulphide.

The *hydrated sulphide*, $ZnS.H^2O$, obtained by precipitation (p. 1071), and dried at 100°, is a white powder, which, when more strongly heated, gives off its water and turns yellowish. It oxidises quickly on exposure to the air, and dissolves easily in dilute mineral acids, slightly in a large excess of acetic acid. (Wackenroder.)

Oxysulphides.—Zinc-sulphide, when dried in the air, generally contains a small quantity of oxide. Oxysulphides of zinc are found in furnace-flues. Kersten (Schw. J. lvii. 186) found one in a furnace at Freiberg, having the composition $ZnO.4ZnS$; the zinc-oxide was not dissolved out of it by acetic acid. The same compound occurs, as voltzite or voltzine, in implanted spherical globules with galena, blende, &c., at Rosières in Puy-de-Dôme, and in the Elias mine, near Joachimsthal in Bohemia.

---

* For references, see Rammelsberg's *Mineralchemie*, p. 48.

† Lead.

The compound Zn^2OS, or $ZnO.ZnS$, is formed, according to Arfvedson (Pogg. Ann. l. 59), when dry zinc-sulphate is heated to redness in a stream of hydrogen.

Pentasulphide of Zinc, ZnS^5, is formed, according to Schiff (Ann. Ch. Pharm. cxv. 74), when a neutral zinc-salt is precipitated by pentasulphide of potassium. The precipitate is white, but acquires a straw-yellow colour when pressed and dried. When heated in a close vessel, it is resolved into the protosulphide and free sulphur. It dissolves in acids, with evolution of sulphydric acid gas, and separation of sulphur.

ZINC, TELLURIDE OF. Zinc and tellurium unite when fused together, with great evolution of heat. The product is grey, crystalline, difficult to fuse, insoluble in dilute sulphuric or concentrated hydrochloric acid. (Berzelius.)

ZINCACETAMIDE, $C^4H^8Zn''N^2O^2$, is a white powder formed by the action of acetamide on zincethyl.

ZINCAMIDE, N^2H^4Zn'', is produced by the action of ammonia on zincethyl (p. 1076).

ZINCAMYL, or **ZINCAMYLIDE.** See ZINC-RADICLES, ORGANIC.

ZINC-ASH. The impure grey oxide, or suboxide of zinc, formed when zinc is heated in contact with the air.

ZINCAZURITE. This name is given by Breithaupt (Berg- u. Hüttenm.-Zeit. vi. 101), to a blue mineral occurring in the veins of Baranco Jaroso, in the Sierra Almagrera in Spain, and containing, according to Plattner and Richter, cupric oxide, zinc-oxide, sulphuric acid, and a little water.

ZINCBLENDE. Native sulphide of zinc (p. 1074).

ZINC-BLOOM, or **ZINCONISE.** A native hydrocarbonate of zinc. (See CARBONATES, i. 798).

ZINC-BUTTER. *Butyrum Zinci.*—Syn. with ZINC-CHLORIDE (p. 1069).

ZINC-DINITROETHYLATE. (See p. 1077.)

ZINCETHYL, or **ZINCETHIDE.** See ZINC-RADICLES, ORGANIC (p. 1076).

ZINC-ETHYLAMYLATE. (See p. 1077.)

ZINC-FAHLORE, or copper-blende from near Freiberg, is a tennantite (p. 720), having the iron partly replaced by zinc.

ZINC-FLOWERS. *Flores Zinci.*—Zinc-oxide produced by combustion of the metal (p. 1073).

ZINC-GLASS. }
ZINC-GRAMMATITE. } Syn. with SILICEOUS CALAMINE (i. 713).

ZINCITE, or *Red Zinc Ore.* Native oxide of zinc containing manganese (p. 1074).

ZINCKENITE. Syn. with ZINKENITE (p. 1079).

ZINC-METHYL, or **ZINC-METHIDE.** See ZINC-RADICLES, ORGANIC (p. 1078).

ZINCONISE. Syn. with ZINC-BLOOM.

ZINC-PHENYLAMIDE. A product of the action of zincethyl on aniline.

ZINCPHYLLITE. Syn. with HOPEITE (iii. 106).

ZINC-RADICLES, ORGANIC. Zinc unites with alcohol-radicles (methyl, ethyl, and amyl), forming compounds analogous in composition to zinc-chloride, or zinc-oxide, and represented by the general formula $Zn''R^2$. They are saturated compounds, not capable of uniting directly with oxygen, chlorine, or other elements, and are therefore not radicles in the proper sense of the word, like cacodyl, stibtrimethyl, stannethyl, &c. They are produced by heating zinc with the iodides of the alcohol-radicles in sealed tubes, and by the action of zinc on the mercury-compounds of the same radicles. The first method is best adapted for the preparation of zincethyl, the second for obtaining the methyl- and amyl-compounds. (See ORGANO-METALLIC BODIES, iv. 219).

Zincamyl, or **Zincamylide,** $Zn(C^5H^{11})^2$.—Prepared by heating zinc with mercuric amylide

$$Hg(C^5H^{11})^2 + Zn^2 = Zn(C^5H^{11})^2 + ZnHg.$$

It is a colourless, transparent, mobile liquid, of specific gravity 1·022 at 0°, boiling at 220°. Vapour-density, obs. = 6·95; calc. (2 vols.) = 6·87. It decomposes gradually at 240°, yielding amylene and amylic hydride. In contact with the air it fumes, but does not take fire. When dropped into oxygen-gas, it burns with a dazzling white

ame and slight explosion. Its reactions with oxygen
isely analogous to those of zincethyl (iv. 225).

Zincethyl, or **Zincethide,** $Zn(C^2H^5)^2$.—This body
1849, is prepared by heating zinc, in a closed vessel, w
ether (iv. 219). For preparation on the small scale, th
glass tubes, and heated in an oil- or air-bath; for large
trived by Frankland, and described in the article BATH
(Ann. Ch. Pharm. cxviii. 22; cxxi. 105), dehydrates equ
iodide with phosphoric anhydride, and heats the mixtu
with carbonic anhydride at a pressure about one-fourth g
air,—with granulated zinc previously strongly etched
thoroughly dried.—Rieth and Beilstein (*ibid.* cxx
alloy of 4 pts. zinc and 1 pt. sodium with ethylic iod
bonic anhydride. Chapman adopts a very similar pr
start the reaction (*Laboratory*, i. 195). Alexeyeff a
lxiii. 171) heat 100 grms. ethylic iodide, in a simil
zinc-sodium, and 70 to 80 grms. zinc-cuttings.—Zince
heating granulated zinc with about half its volume
retort in the water-bath for 36 hours (Frankland an
3).—Zincethyl is also produced by the action of zinc
(Wanklyn):

$$Zn + Hg + 2NaC^2H^5 = Zn(C^2H$$

Zincethyl is a transparent, colourless, strongly refra
odour rather agreeable than otherwise. Specific gravit
solidify at −22°, boils at 118°, and distils without d
obs. = 4·259; calc. (2 vols.) = 4·262. In contact wi
takes fire, burning with a bright-green-edged flame, and
zinc-oxide. It is also rapidly decomposed by water, wi
and zinc-hydrate:

$$Zn(C^2H^5)^2 + 2H^2O = 2(C^2H^5.H)$$

The reactions of zincethyl with oxygen, the halo
oxide, phosphorous chloride, oxalic ether, ammonia, &c
under ORGANO-METALLIC BODIES (iv. 225, 226). We
covered since that article was written:—

With *chloride of acetyl* and its homologues, zincethyl
alcohols, according to the manner in which the react
chloride of acetyl is added by drops to 1 at. zinceth
to 0° and filled with carbonic anhydride, a strong action
be immediately treated with water, a ketone boiling a
composition of acetyl-ethyl, $C^4H^8O = C^2H^3O.C^2H$
seems to take place between 2 at. chloride of acetyl and

$$2C^2H^3OCl + Zn(C^2H^5)^2 = ZnCl^2 +$$

But if the liquid be left to itself for some days, it bec
warmed and treated with water, a large quantity of co
the liquid, acidulated with hydrochloric acid and disti
homologous with pseudobutylic alcohol—viz., methyl
$\left.\begin{matrix}[C(CH^3)(C^2H^5)^2]'\\ H\end{matrix}\right\}O.$ (See the corresponding reaction

Chloride of butyryl, C^4H^7OCl, yields with zince
butyryl-ethyl, $C^4H^7O.C^2H^5$, or propyl-diet
$\left.\begin{matrix}[C(C^3H^7)(C^2H^5)^2]\\ H\end{matrix}\right\}O.$ (Freund, Ann. Ch. Pharm. cxvi
Buttlerow, Bull. Soc. Chim. 1866, i. 17; Jahresb. 18
benzoyl, zincethyl yields benzoyl-ethyl, $C^7H^5O.C^2H$
Ann. Ch. Pharm. cxix. 165).—With *phenylsulphurous c*
chloride and phenylsulphurous hydride. (Kalle.)

2. When zincethyl is heated in sealed tubes with *all*
tion takes place, resulting in the formation of ethy
iodide, allyl, C^6H^{10}, amylene, C^5H^{10}, amylic hydride,
(Wurtz, Ann. Ch. Pharm. cxxiii. 202).—Zincethyl, h
to 120°, yields a liquid which has an alliaceous odour,
80°. (Olevinsky, Jahresb. 1861, p. 664.)

3. *Tetrachloride of carbon* acts strongly on zincethyl,
and propylene (Rieth and Beilstein, Ann. Ch.

$$2CCl^4 + 3Zn(C^2H^5)^2 = 2C^2H^5Cl + 2C^2H$$

4. *Chloroform* acts less strongly, producing amylene, and probably ethylic hydride, together with small quantities of ethylene and propylene (Reith and Beilstein).—With *bromoform* a strong action takes place, resulting in the formation of propylene and ethylic bromide (Alexeyeff and Beilstein, Compt. rend. lviii. 172):

$$CHBr^3 + Zn(C^2H^5)^2 = C^3H^6 + C^2H^5Br + ZnBr^2.$$

Iodoform likewise acts strongly on zincethyl, apparently combining directly with it.

5. *Chloriodoform*, added by drops to zincethyl, forms chloride and iodide of zinc, together with ethylene, ethyl (tetrylic hydride), and free hydrogen (Borodine, Ann. Ch. Pharm. cxxvi. 239):

$$2CHCl^2I + 3Zn(C^2H^5)^2 = 7C^2H^4 + 2H^2 + 2ZnCl^2 + ZnI^2.$$
$$2CHCl^2I + 3Zn(C^2H^5)^2 = 3C^2H^4 + 2C^4H^{10} + 2ZnCl^2 + ZnI^2.$$

6. *Dichloride of carbon* does not act on zincethyl under the ordinary atmospheric pressure.—*Trichloride of carbon* is reduced to dichloride, with formation of ethylic chloride and zinc-chloride.

7. Zincethyl is not attacked by *chloride of triethylstibine*, $Sb(C^2H^5)^3Cl^2$, even at the boiling heat; but with the *iodide* it appears to form antimonic pentethide, $Sb(C^2H^5)^5$, which is then decomposed according to the equation:

$$Sb(C^2H^5)^5 = Sb(C^2H^5)^3 + C^2H^4 + C^2H^6.$$

(Buckton, Chem. Soc. Qu. J. xiii. 125.)

8. Pure zincethyl attacks *amylic nitrite* with great violence, bursting out into flame when placed in contact with it. But if the zincethyl be considerably diluted with ether, and added to an excess of amylic nitrite, nitric oxide is evolved, and a honey-like mass is formed, which, on treatment with water, yields amylic alcohol, ethylic alcohol, ethylic hydride, and probably ethyl-amylic ether, thus:

$$2NO(C^5H^{11})O + Zn(C^2H^5)^2 = \underbrace{\left.\begin{matrix}ZnC^2H^5\\ C^5H^{11}\end{matrix}\right\}O \cdot \left.\begin{matrix}C^2H^5\\ C^5H^{11}\end{matrix}\right\}O}_{\text{Honey-like mass.}} + 2NO.$$

$$\underset{\text{Zincethyl-amylate.}}{Zn(C^2H^5)(C^5H^{11}O)} + 2H^2O = \underset{\text{Zinc-hydrate.}}{Zn(HO)^2} + \underset{\text{Ethyl-hydride.}}{C^2H^6} + \underset{\text{Amyl-alcohol.}}{C^5H^{12}O.}$$

The ethylic alcohol is probably formed by the action of water on the ethyl-amyl-ether, $(C^2H^5)(C^5H^{11})O$, contained in the honey-like substance.—When amylic nitrite is dropped into excess of zincethyl diluted with five or six times its weight of ether no gas is evolved; but, nevertheless, the action appears to be the same as that just described, excepting that the nitric oxide produced is immediately absorbed by the excess of zincethyl, forming the compound of zinc-dinitroethylate with zincethyl described under DINITROETHYLIC ACID (iv. 61).—When only a small quantity of ether is mixed with the zincethyl, triethylamine is formed, as shown by the equation:

$$N'''\left\{\begin{matrix}O''\\ OC^5H^{11}\end{matrix}\right. + 3\ \frac{Zn}{2}\ C^2H^5) = \frac{ZnO}{\frac{Zn}{2}OC^5H^{11}} + N(C^2H^5)^3.$$

(Chapman and Smith, Chem. Soc. J. vol. xxi. 1868.)

9. When *amylic nitrate* is mixed with undiluted zincethyl in an atmosphere of carbonic anhydride, no change takes place at first; but if the mixture be exposed for an instant to the air, it explodes with a vivid flash of light and sharp report, and with extreme violence if heated to about 40°. Dilution with ether renders the reaction manageable, and if the mixture be then heated to 110°, complete decomposition takes place. (Chapman and Smith.)

Respecting the action of zincethyl on other compound ethers, see ORGANO-METALLIC BODIES (iv. 226), and OXALIC ETHERS (iv. 272).

10. With *monochlorinated ethylic oxide*, zincethyl yields a liquid having the composition $C^6H^{13}ClO$, apparently $C^4H^8Cl(C^2H^5)O$, or monochlorethylic oxide having one atom of the hydrogen replaced by ethyl. (Lieben and Bauer, Ann. Ch. Pharm. cxxiii. 130.)

11. Zincethyl, gently heated for some hours with *aldehyde*, forms a compound having nearly the composition of acetal.—On *valeral* and *œnanthol* it appears to exert a dehydrating action (Rieth and Beilstein).—*Bitter-almond oil* is strongly attacked by zincethyl.—*Acetone* acts strongly on zincethyl, especially when heated, forming an oil having, in general, the properties and nearly the composition of phorone, $C^9H^{14}O$.

12. An ethereal solution of zincethyl, added in excess to *amylene disulphochloride* (i. 209), separates into two layers; and on adding water, and drying and distilling the oil which floats on the surface, the compound $C^{10}H^{20}S^2Cl^2$ passes over between 240° and 250°. (Guthrie, Ann. Ch. Pharm. cxxi. 108.)

13. *Carbonic disulphide* unites with zincethyl, formin
as a brown shining mass, which gives off sulphide of a
(Grabowski, Ann. Ch. Pharm. cxxxviii. 165; Jahresb

Zinc-methyl, or **Zinc-methide,** $Zn(CH^3)^2$.—This
Frankland in 1849, is formed by heating methylic iodid
150°; but the method is not advantageous, since a la
formed, and escapes forcibly on opening the tube, carr
The preparation is greatly facilitated by mixing the met
its bulk of ether, and heating to 100° in the copper app
of zincethyl (p. 1076). On rectifying the product, a liq
consisting of zinc-methyl, mixed or combined with et
$Zn(CH^3)^2$ to 1 at. $(C^2H^5)^2O$.—When methylic ether, con

nor the methylic ether can be separated from the zinc-m
Pharm. cxi. 62). Pure zinc-methyl may, however, be
zinc-methyl and ethylic ether just mentioned, by enclosi
and methylic iodide, heating the mixture to 100°, and d
tillate contains a larger proportion of zinc-methyl than
repeating the process a certain number of times, nearly
(Wanklyn, Chem. Soc. Qu. J. xiii. 124). According
however (Chem. Soc. J. xvii. 30), the best mode of prep
heat finely-granulated zinc with half its volume of merc
to 120° for 24 hours, and distil off the product.

Zinc-methyl is a colourless liquid, of specific gravity
stantly at 46° (Frankland and Duppa). Vapour-densit
3·296. The vapour bears a temperature of 200° witho
it decomposes, with separation of zinc and gaseous hyd

Zinc-methyl takes fire immediately in contact with th
greenish-blue flame; in oxygen-gas it burns with expl
vapour mixed with combustible gases render them spon

In its chemical reactions, zinc-methyl exhibits for the
zincethyl; in some cases, however, differences are obser
dride (iii. 1003; iv. 225).—*Water* decomposes zinc-met
gas (methylic hydride), and separation of zinc-hydrate.

With *chloride of lead*, zinc-methyl forms plumbic d
chloride, with separation of lead. (Buttlerow, Bull.

An ethereal solution of zinc-methyl added to *iodide*
ethide, $Sn^{iv}(C^2H^5)^2I^2$, forms iodide of zinc and stannic eth

With *mercuric chlorethide*, zinc-methyl appears to form
ethylomethide, $Hg(C^2H^5)(CH^3)$, which however is resolv
mercuric ethide and mercuric methide.

Antimonic di-iodotrimethide, $Sb(CH^3)^3I^2$, acts strong
zinc-methyl, forming antimonious methide (stibmethyl),
tamethide, $Sb(CH^3)^5$, which cannot be completely s
(Buckton, Chem. Soc. Qu. J. xiii. 115.)

With *chloride of acetyl* and its homologues, zinc-met
ing acetones or tertiary alcohols, according as the prod
with water immediately, or after some time only. In
the product formed in the first case is ordinary acetone,
but when the liquid formed by gradually adding 1 at. cl
methyl, is left to itself for a few hours, it solidifies to lar
pound $C^6H^{15}Zn^2OCl = C^2H^3OCl \cdot 2Zn(CH^3)^2$. The
take place in the manner represented by the equation
$\left.\begin{matrix}[C(CH^3)^2]' \\ (CH^3Zn)'\end{matrix}\right\}O + (CH^3Zn)'Cl$, inasmuch as the crystals
resolved into marsh-gas, zinc-hydrate, zinc-chloride, an
methyl-carbinol):

$$\left.\begin{matrix}C(CH^3)^3 \\ CH^3Zn\end{matrix}\right\}O + CH^3ZnCl + 4H^2O = \left.\begin{matrix}C(CH^3)^3 \\ H\end{matrix}\right\}O$$

With *chloride of butyryl*, in like manner, zinc-meth
thyl, $C^4H^7O.CH^3$, or tertiary octylic alcohol (propyl
$\left.\begin{matrix}C(C^3H^7)(C^2H^5)^2 \\ H\end{matrix}\right\}O$. (Buttlerow, Zeitschr. Ch. Pharm
1864, p. 496; Bull. Soc. Chim. 1866, i. 17; Jahresb. 186

With *chloride of carbonyl* (phosgene), zinc-methyl form which, when treated with water, yields a distillate, apparently consisting of the compounds $C^4H^{10}O$ and C^3H^8O.

Ethylic chlorocarbonate (i. 916) is strongly attacked by zinc-methyl at a gentle heat, yielding zinc-chloride, carbonic anhydride, ethylene, and marsh-gas.—With *methylic chlorocarbonate*, the action is similar, but less energetic; the substances must be heated together in a sealed tube, and even then the decomposition is not complete. (Butlerow, Bull. Soc. Chim. 1863, p. 588.)

ZINC-SPAR. Syn. with CALAMINE (i. 713).

ZINC-SPINEL. Syn. with GAHNITE (ii. 757).

ZINCUM. Syn. with ZINC (p. 1067).

ZINC-VITRIOL. Syn. with ZINC-SULPHATE. (See SULPHATES, p. 617).

ZINC-VITRITE. Syn. with SILICEOUS CALAMINE (i. 714).

ZINC-WHITE. Zinc-oxide used as a pigment (p. 1073).

ZINGIBER. See GINGER (ii. 838).

ZINKENITE. $Pb''Sb^2.S^4 = Pb''S.Sb^2S^3$. *Zinckenite. Rhombohedral Dystomeglance.*—A sulphantimonite of lead, occurring in the antimony-mine at Wolfsberg in the Harz, in trimetric crystals, usually in twins, as hexagonal prisms terminated by low hexagonal pyramids; lateral faces longitudinally striated; sometimes columnar, fibrous, or massive. Cleavage not distinct. Hardness = 3 to 3·5. Specific gravity = 5·30 to 5·35. Lustre metallic. Colour and streak steel-grey. Opaque. Fracture slightly uneven. (H. Rose, Pogg. Ann. viii. 99.—Brun Kerl, Berg. u. hüttenm. Zeit. 1853, No. 2.—Dana, ii. 74.)

ZIPPEITE. A basic uranic sulphate found at Joachimsthal in Bohemia.

ZIRCON. ZIRCONITE. $ZrSiO^4 = ZrO^2.SiO^2$. *Jargon. Hyacinth.*—A mineral occurring in quadratic crystals, the predominant faces of which are P, ∞P, ∞P∞. Length of principal axis = 0·6405. Angle P : P (terminal) = 123° 19′; P : P (lateral) = 84° 20′. Cleavage imperfect parallel to ∞P. Occurs also in irregular forms and in grains. Hardness = 7·5. Specific gravity = 4·0—4·75. Lustre more or less adamantine. Colour red, brown, yellow, grey, or white. Streak uncoloured. Transparent to subtranslucent. Fracture conchoïdal and brilliant. Before the blowpipe it loses colour, but is infusible alone, also with sodium-carbonate and microcosmic salt. With borax it melts with difficulty to a diaphanous glass, which, with more of the flux, is opaque.

Pure zircon contains 33·2 per cent. silica and 66·8 zirconia; some specimens contain small quantities of lime and ferric oxide.

The name *hyacinth* includes the bright-coloured varieties of zircon, which are sometimes large enough to be valuable as gems; the greyish or brownish kinds are called *zirconite*. A variety from Ceylon, which is colourless or has only a smoky tinge, and is therefore sold for inferior diamonds, is sometimes called *jargon*.

Hyacinth occurs in the sand and alluvial deposits of certain rivers in Ceylon; at Expailly, near La Puy, in France; at Ohlapian in Transylvania, Pfitsch in the Tyrol, Bilin in Bohemia, Lebnitz in Saxony, occasionally in volcanic tufa in Auvergne; also in Greenland; in the zircon-syenite of Frederichsvärn in Norway; near Brevig, sometimes called *Erdmannite*; at Miask, in the Urals; in the iron-mines of Arendal; also in Scotland, at Scalpay in Harris, and in the granite of Criffel in Kirckudbrightshire; on Vesuvius, with ryacolite, in white and blue octahedrons; at Santa Rosa, in New Granada, in small colourless crystals; and at several localities in North Carolina, New York, New Jersey, Pennsylvania, California, and Canada (Dana, ii. 196).—Breithaupt's *Ostranite*, supposed to be from Frederichsvärn, is a greyish-brown zircon.

Zircon is one of the most unalterable of minerals, but is sometimes found in a hydrated state, and is probably acted upon by alkaline waters, which take up part of the silica: *calypolite* (i. 723), *malacone* (iii. 784), *œrstedtite* (iv. 179), and *tachyaphaltite* (v. 654), appear to be zircons thus altered.

ZIRCONATES. See ZIRCONIUM, OXIDE OF (p. 1084).

ZIRCONIA. Oxide of Zirconium (p. 1083).

ZIRCONIC ACID. Zirconia in combination with bases (p. 1084).

ZIRCONITE. See ZIRCON.

ZIRCONIUM. *Symbol*, Zr; *Atomic Weight*, 89·6.—An element belonging to the group of earth-metals, and apparently forming a link between aluminium and silicium. Its oxide, zirconia, was first obtained from zircon, and recognised as a peculiar substance by Klaproth, in 1789; it has since been found in eudialyte, polymignite, œrstedtite, fergusonite, and catapleïite. Aschynite, formerly supposed to contain zirconium, has been shown, by recent experiments of Hermann (Bull. Soc. Chim. 1866, ii. 386) to be free from it.

Metallic zirconium is capable, like silicium, of existing in three states—amorphous, crystalline, and graphitoïdal.—*Amorphous zirconium* was obtained by Berzelius (in 1824), in the same manner as amorphous silicium and boron—namely, by heating a mixture of potassio-zirconic fluoride with potassium, digesting the fused mass with water containing a little hydrochloric acid, and washing the metal which remains undissolved with sal-ammoniac solution, and then with alcohol. It may also be prepared by passing chloride of zirconium in vapour over sodium contained in a red-hot porcelain tube, or by heating sodio-zirconic chloride in a crucible with sodium or magnesium (Troost, Compt. rend. lxi. 109; Bull. Soc. Chim. 1866, i. 213). Zirconium thus obtained is an amorphous powder, compressible under the burnisher into thin, faintly lustrous, graphitic laminæ. In the unignited state it diffuses itself through water in extremely fine particles, which pass through a filter; but it settles down slowly on standing, more quickly on addition of acids or salts. It does not conduct electricity, is not altered by ignition in hydrogen; but if it be then brought in contact with the air, after cooling, the metal becomes heated to redness, in consequence of the heat evolved by the absorption of the air. When heated in the air, it takes fire at a heat considerably below redness, and burns with a bright light, forming zirconia. It is but little attacked by the ordinary acids, or by nitromuriatic acid; but hydrofluoric acid dissolves it readily, with evolution of hydrogen, and a mixture of hydrofluoric and nitric acids attacks it very energetically.

Crystalline zirconium is prepared by heating 1 pt. of potassio-zirconic fluoride with 1½ pt. aluminium in a plumbago crucible, to the melting-point of iron. When the crucible has cooled, the surface of the aluminium is found to be covered with foliated crystalline laminæ, consisting of nearly pure zirconium, which may be separated by dissolving out the aluminium with hydrochloric acid. Crystalline zirconium thus obtained is very hard, and resembles antimony in colour, lustre, and brittleness. It crystallises in broad laminæ, apparently derived from a monoclinic prism. Specific gravity = 4·15. It is less fusible than silicium, and burns only at the temperature of the oxyhydrogen-blowpipe. It takes fire at a red heat in chlorine-gas, and decomposes hydrochloric acid gas at the same temperature. It is but slowly attacked by sulphuric, nitric, or hydrochloric acid, even when heated; hot nitromuriatic acid attacks it rapidly; hydrofluoric acid also dissolves it readily, even in the cold. (Troost.)

Graphitoïdal zirconium appears to be formed only under peculiar circumstances. Troost, in attempting to decompose zirconate of sodium with iron, obtained zirconium in small very light scales, of a steel-grey colour.

Zirconium is a tetratomic element, like silicium, its oxide being ZrO^2, the chloride $ZrCl^4$, &c. It forms but one class of compounds with chlorous elements. The oxide is capable of acting both as a base and as an acid.

ZIRCONIUM, BROMIDE OF. A solution of zirconium-hydrate in hydrobromic acid leaves, on evaporation, a hydrated bromide in crystalline grains, which are resolved by heat into zirconia and hydrobromic acid. (Berzelius.)

ZIRCONIUM, CHLORIDE OF. $ZrCl^4$.—This compound is formed, with incandescence, when zirconium is heated in chlorine-gas; also by heating a mixture of zircon or zirconia with charcoal, in a stream of dry chlorine, in which case it collects in the cooler part of the apparatus as a white sublimate. Its vapour-density, as determined by Deville and Troost (Ann. Ch. Pharm. cv. 213), is 8·15; by calculation from the formula, $ZrCl^4$, for a two-volume condensation, it is 8·0. The chloride dissolves easily, and with rise of temperature, in water.

A *hydrated chloride* is obtained, by evaporating a solution of zirconic hydrate in hydrochloric acid, in colourless silky needles, having an astringent taste, easily soluble in water and in alcohol, sparingly soluble in concentrated hydrochloric acid. (Berzelius.)

These crystals become opaque at 50°, giving off part of their water and half their hydrochloric acid, and leaving a basic chloride or oxychloride containing $ZrCl^4.ZrO^2.18H^2O$, or $ZrOCl^2.9H^2O$. The same compound is obtained, in stellate groups of white silky prisms, on evaporating the aqueous solution of zirconium-chloride. These crystals, when heated, become white and turbid, and are converted into the anhydrous dioxychloride $ZrCl^4.2ZrO^2$. (Hermann.)

ZIRCONIUM, DETECTION AND ESTIMATION OF. The reactions of zirconium-salts with alkalis, alkaline carbonates, and ammonium-sulphide are very similar to those of thorinum, yttrium, and the metals of the cerium-group. The precipitate formed by *caustic alkalis* and *ammonia* contains alkali, and is insoluble in excess of the reagent (distinction from aluminium and glucinum), also in sal-ammoniac. The precipitate formed by *alkaline carbonates* and *bicarbonates* redissolves in excess of the reagent.—A characteristic reaction is afforded by a hot concentrated solution of *potassic sulphate*, which, when added to a hot solution of a zirconium-salt, throws down the zirconium as basic potassio-zirconic sulphate, insoluble in water, and nearly insoluble even in a large quantity of hydrochloric acid.—Zirconium is precipitated from its solution by boiling with *hyposulphite of sodium*, a character by which it may be distinguished from yttrium and the cerium-metals. From cerium and from didymium it is further distinguished by not giving any coloured reactions before the blowpipe. The methods of distinguishing it from thorinum have already been given (p. 786).

For the *quantitative estimation* of zirconium in solutions containing only volatile acids, it is sufficient to evaporate to dryness, and ignite the residue, whereby zirconia is obtained, containing 73·68 per cent. of the metal. Zirconium may also be precipitated from such solutions by ammonia as a basic salt, which also leaves pure zirconia when ignited.

From yttrium, the cerium-metals, and iron, zirconium may be separated by boiling the solution with *hyposulphite of sodium*, which precipitates the zirconium alone as hyposulphite. This precipitate when ignited leaves pure zirconia. To effect complete separation from the cerium-metals by this method, the solution must be dilute. For separating zirconium from iron (as ferric salt) by the same method, Chancel (Ann. Ch. Pharm. cviii. 237) and Stromeyer (*ibid.* cxiii. 127) recommend that the dilute solution, after being nearly saturated with sodic carbonate, be mixed cold with sodic hyposulphite till it is completely decolorised; if the liquid be then boiled as long as sulphurous anhydride continues to be evolved, the zirconium is completely precipitated as oxide, while the whole of the iron remains dissolved as ferrous salt. The separation of zirconium from these metals may also be effected by treating the boiling solution with *sulphate of potassium*, and adding a drop or two of ammonia, whereby the zirconium is precipitated, and the other metals remain dissolved. (H. Rose.)

Precipitation with *hyposulphite of sodium* serves also to separate zirconium from phosphoric and boric acids.

From thorinum, zirconium is separated by *oxalate of ammonium*, which, when added in excess, precipitates the thorinum as oxalate, and holds the zirconium in solution.

From titanium, tantalum, and niobium, zirconium may be separated by precipitation with *sulphate of potassium*.

Atomic Weight of Zirconium.—Berzelius (Pogg. Ann. iv. 124; viii. 186) found that sulphate of zirconium contains 75·583 pts. zirconia to 100 pts. sulphuric anhydride (mean of eight experiments). Hence the atomic weight of zirconium is 44·7, 67·0, or 89·4, according as zirconia is regarded as ZrO, Zr^2O^3, or ZrO^2. Hermann (J. pr. Chem. xxxi. 77), by the analysis of chloride of zirconium, obtained very nearly the same numerical results. Now the vapour-density of the chloride calculated from the formula $ZrCl^4$, with $Zr = 89·4$, for a two-volume condensation, agrees very nearly with the experimental number obtained by Deville and Troost (p. 1080); and Marignac has shown that double-salts of zirconium-fluoride are isomorphous with those of silicium-fluoride. Hence zirconium is regarded as a tetratomic element, having the atomic weight 89·4.

ZIRCONIUM, FLUORIDE OF. ZrF^4.—Strongly ignited zirconia dissolves with difficulty in hydrofluoric acid: the hydrate dissolves abundantly. *Anhydrous zirconium-fluoride* is formed by heating zirconia with twice its weight of ammonium-hydrogen-fluoride (ii. 670), till the fluoride of ammonium is completely driven off. It dissolves readily in water acidulated with hydrofluoric acid; and when its solution containing excess of hydrofluoric acid is evaporated, *hydrated zirconium-fluoride*, $ZrF^4.3H^2O$, separates out in small, shining, triclinic crystals, mostly of the tabular form. They give off hydrofluoric acid as well as water when heated, and if the heat be continued for some time (even below redness), pure zirconia remains behind. Fluoride of zirconium dissolves without decomposition in dilute hydrofluoric acid, but when it is dissolved in pure water, a basic fluoride or oxyfluoride separates out. (Marignac.)

Fluozirconates.—Zirconium-fluoride unites with many other metallic fluorides, forming double salts isomorphous with the corresponding fluosilicates (silicofluorides, p. 271), fluostannates (p. 813), and fluotitanates (p. 840). The ratio of the fluorine of the zirconium-fluoride to that of the basic metallic fluoride in these salts is as 1 : 1; 1 : $1\frac{1}{3}$; 1 : 2; and 1 : 4; the sodium-salt alone exhibiting the ratio 5 : 8. The general formulæ of the fluozirconates are, therefore, $4MF.ZrF^4$, $3MF.ZrF^4$, $2MF.ZrF^4$, and $MF.ZrF^4$, the sodium-salt alone having the formula $5NaF.2ZrF^4$. The fluozirconates have been examined chiefly by **Marignac.** (Ann. Ch. Phys. [3], lx. 257; Ann. Ch. Pharm, cxv. 359; Jahresb. 1860, p. 136, *et seq.*)

The fluozirconates are mostly soluble in water, and crystallise well. They are prepared by mixing the component fluorides, or by dissolving a metallic oxide or carbonate in a mixture of zirconium-fluoride and hydrofluoric acid.

The fluozirconates of barium, strontium, and calcium are insoluble in water; consequently the solutions of fluozirconates are precipitated by salts of these metals. When a solution of zirconium-fluoride containing free hydrofluoric acid is mixed with carbonate of barium, carbonic anhydride is expelled, and a precipitate is formed, consisting of a mixture of insoluble barium-zirconium fluoride with insoluble barium-fluoride; similarly with the carbonates of strontium and calcium.

Many fluozirconates dissolve without decomposition in water, either hot or cold. Many are decomposed when their aqueous solutions are boiled, part of the basic metallic fluoride being deposited, and a fluozirconate containing $2MF.ZrF^4$ remaining in solution. Most fluozirconates, when heated in contact with moist air, give off all their fluorine as hydrofluoric acid, leaving a mixture of zirconia and the oxide of the other metal; when heated with a sufficient quantity of sulphuric acid, they yield a mixture of zirconium-sulphate with the sulphate of the other metal.

Fluozirconates of Ammonium.—The *diammonic salt*, $2(NH^4)F.ZrF^4$, forms rhombic crystals, isomorphous with the potassium-salt: they do not lose weight at 100°.—The *triammonic salt*, $3(NH^4)F.ZrF^4$, crystallises from a solution containing a large excess of ammonium-fluoride, in regular cubo-octahedrons.

Barium-salt.—A solution of the potassium-salt, mixed with chloride of barium, yields a white precipitate, consisting of $3Ba''F^2.2ZrF^4.2H^2O$, or perhaps a mixture of this salt with barium-fluoride.

Cadmium-salts.—The *dicadmic salt*, $2CdF^2.ZrF^4.6H^2O$, forms monoclinic crystals isomorphous with the manganese-salt, and having the angle $\infty P : \infty P = 79° 31'$; $+P : +P = 100° 30'$; $+2P : +2P = 75° 24'$; $oP : \infty P = 108° 29'$; $oP : \infty P\infty = 119° 43'$; the same crystals are obtained by recrystallisation from water. A solution containing excess of zirconium-fluoride deposits the salt $CdF^2.2ZrF^4.6H^2O$, in fan-shaped groups of laminar crystals.

Copper-salts.—The *tricupric salt*, $3CuF^2.2ZrF^4.16H^2O$, forms monoclinic crystals, and crystallises unaltered from solution in water; but a solution containing excess of zirconium-fluoride deposits, besides the larger crystals of this salt, light-blue crusts of zirconium-fluoride contaminated with adhering copper-salt.

Lead-salt.—When a solution of zirconium-fluoride in hydrofluoric acid is saturated with carbonate of lead, fluozirconate of lead partly remains undissolved and partly dissolves, the solution yielding on evaporation a granulo-crystalline salt, which is quickly decomposed by water, especially in presence of hydrofluoric acid, with separation of lead-fluoride.

Magnesium-fluozirconate, $MgF^2.ZrF^4$, forms small shining crystals with curved faces, isomorphous with the manganese-salt. It is only sparingly soluble in water, but crystallises by slow evaporation, often in twins. By prolonged heating in contact with the air, it is converted into magnesia and fluoride of zirconium.

Manganese-salts.—The *monomanganous salt*, $MnF^2.ZnF^4.5H^2O$, forms monoclinic crystals, isomorphous with the magnesium-salt, but the faces are flat and more numerous: the crystals cleave imperfectly parallel to oP. By prolonged heating in the air it turns black, and is converted into manganic peroxide and zirconium-fluoride.—A solution containing excess of zirconium-fluoride yields rose-coloured monoclinic crystals of the *dimanganous salt*, $2MnF^2.ZrF^4.6H^2O$, which dissolves in water without alteration, and is not decomposed even on heating the solution; but when hot water is poured upon the crystals, fluoride of manganese separates, and the solution yields by evaporation crystals of the preceding salt.

Nickel-salts.—The *normal salt*, $NiF^2.ZrF^4.6H^2O$, forms hexagonal prisms, terminated by faces of a rhombohedron of 127° 10', and cleaving parallel to the prismatic faces.—The salt $2NiF^2.ZrF^4.12H^2O$, produced in presence of an excess of nickel-fluoride, forms monoclinic crystals of a fine emerald-green colour, but mostly indistinct: they dissolve without decomposition in water, but the solution, when boiled for some time, becomes turbid from separation of nickel-fluoride.

Fluozirconate of Nickel and Potassium, $NiF^2.2KF.2ZrF^4.8H^2O$, separates in small but regular monoclinic crystals, on mixing the solutions of the component fluozirconates. It is slightly soluble in water, does not lose water at 100°, but at a higher temperature gives off water, together with hydrofluoric acid.

Potassium-salts.—The *dipotassic salt*, $2KF.ZrF^4$, may be prepared by igniting zircon with 2 or 3 pts. by weight of acid potassium-fluoride, boiling the resulting mixture of fluosilicate and fluozirconate of potassium with water containing a little hydrofluoric acid, and filtering. The potassium-fluozirconate then separates on cooling, in anhydrous rhombic crystals terminated by six-sided pyramids. It dissolves in 128 pts. of water at 2°, in 71 pts. at 15°, in 59 pts. at 19°, and in 4 pts. at 100°. The crystals when heated to redness form a doughy mass, which, on exposure to moist air, gradually gives off all its fluorine as hydrofluoric acid. From dilute solutions the salt is obtained in larger crystals.—The *monopotassic salt*, $KF.ZrF^4.H^2O$, separates from a solution containing a large excess of zirconium-fluoride, in ill-defined monoclinic crystals, which give off their water at 100°, and hydrofluoric acid at a higher temperature. When recrystallised from water they yield the preceding salt.—The *tripotassic salt*, $3KF.ZrF^4$, crystallises from a solution containing an excess of potassium-fluoride, in very small but well-defined regular octahedrons, or cubo-octahedrons, which decrepitate when heated, but do not contain any water of crystallisation. They dissolve in water, and the hot saturated solution deposits the dipotassic salt on cooling.

Sodium-salt, $5NaF.2ZrF^4$.—This salt is always formed, in whatever proportion the component fluozirconates may be mixed. It forms small, mostly indistinct, monoclinic crystals, soluble in 258 pts. water at 18°, and in about 60 pts. of boiling water. On account of this slight solubility, the salt may be obtained by precipitating the more soluble fluozirconates with chloride of sodium. The dry crystals do not decompose at a red heat.

Zinc-salt, $ZnF^2.ZrF^4.6H^2O$.—This salt, isomorphous with fluosilicate and fluostannate of zinc, crystallises in rather large, regular, hexagonal prisms, terminated by rhombohedrons, and cleavable parallel to the faces of the hexagonal prism; they are very soluble in water. A solution containing excess of zinc-fluoride, deposits the salt $2ZnF^2.ZrF^4.12H^2O$, in monoclinic crystals, isomorphous with the corresponding nickel-salt; they dissolve completely in cold water, but the solution when boiled deposits fluoride of zinc.

ZIRCONIUM, NITRIDE OF. Zirconium strongly ignited in a rapid stream of ammonia-gas, yields a brown or black body containing nitrogen. Mallet (Sill. Am. J. xxviii. 346), by fusing amorphous zirconium with aluminium, in a cracked lime-crucible, obtained a dark-grey porous mass, which, when treated with hydrochloric acid, yielded microscopic cubes, having a golden lustre, not altered by nitromuriatic acid or aqueous alkalis, but giving off ammonia when fused with potassic hydrate.

ZIRCONIUM, OXIDE OF. *Zirconia.* ZrO^2.—This compound, the only known oxide of zirconium, is formed when the metal is heated to redness in contact with the air, or fused with the hydrates, carbonates, or hydrated borates of the alkali-metals. Zirconium is likewise oxidised, though slowly, by boiling with nitromuriatic or concentrated sulphuric acid.

Zirconia is prepared from zircon. The mineral is heated to redness and quenched in water, and the lumps (best those which are colourless, because free from iron) are finely pulverised and levigated. The levigated powder is mixed with four times its weight of sodium-carbonate, and very strongly heated in a platinum crucible. Henneberg and Wackenroder add a small quantity of nitre. Berzelius ignites the pulverised zircon with 3 pts. of sodium-carbonate, and lays small pieces of sodium-hydrate on the ignited mass from time to time, in such a manner that they may not touch the crucible. The pulverised zircon may also be decomposed by fusion with 3 or 4 pts. of sodium-hydrate in a silver crucible.

The disintegrated mass is supersaturated with hydrochloric acid; the liquid evaporated nearly to dryness to separate the silica; the residual mass digested with water; and the filtered solution treated with excess of ammonia, whereby zirconium is precipitated, generally mixed with ferric oxide.

The best method of separating the iron and obtaining pure zirconia, is to redissolve the precipitate in hydrochloric acid, and boil the solution with hyposulphite of sodium, whereby hyposulphite of zirconium is precipitated, while the whole of the iron remains in solution as ferrous salt. The washed precipitate is then boiled with hydrochloric acid as long as sulphurous acid continues to be evolved, and the solution of zirconium-chloride thus obtained is mixed with ammonia, whereby the zirconium is precipitated as a hydrate, which, when ignited, leaves anhydrous zirconia (Hermann). If the treatment with hyposulphite of sodium be conducted in the manner recommended by Chancel and Stromeyer (p. 1081), a precipitate of anhydrous zirconia is at once obtained.

The iron may also be precipitated by mixing the solution of zirconium-chloride containing iron with tartaric acid, then supersaturating with ammonia, and adding sulphide of ammonium. The iron is thereby precipitated as sulphide, and the filtered liquid, evaporated and ignited in contact with the air, leaves pure zirconia. [For other methods of separation, see Handw. d. Chem. ix. 1059; Gmelin's Handbook, iii. 340.]

Marignac decomposes zircon by ignition with hydrogen-ammonium-fluoride in the manner already described (p. 1081), heats the fluozirconate of potassium thereby obtained with strong sulphuric acid, and washes the strongly ignited residue with boiling water; pure zirconia then remains behind.

Zirconia, according to the mode in which it has been prepared, forms a white, tasteless, inodorous powder, or hard lumps of specific gravity 4·35 to 4·9, which scratch glass and give sparks with steel. Deville and Caron (Ann. Ch. Pharm. cviii. 55), by igniting fluoride of zirconium with borax in a closed crucible lined with charcoal, obtained zirconia in dendritic groups of small crystals resembling sal-ammoniac. When zirconia is fused with borax in a pottery-furnace, and the residue exhausted with hydrochloric acid, the zirconia remains in transparent, colourless, microscopic, quadratic prisms, isomorphous with tinstone and rutile, having a specific gravity of 5·71 to 5·72, and capable of polarising light. (Nordenskjöld, Pogg. Ann. cxiv. 612.)

When zirconia, prepared at the lowest possible temperature, is heated to commencing redness, it glows brightly, becomes dense, and is afterwards insoluble in ordinary acids, dissolves with difficulty even in hydrofluoric acid, and can be dissolved only by strong sulphuric acid, the finely pulverised earth being heated with a mixture of 2 pts. oil of vitriol and 1 pt. water. By ignition with charcoal in a stream of chlorine, zirconia is converted into chloride of zirconium.

Hydrate of Zirconia, or *Hydrate of Zirconium*, is precipitated from zirconium-salts by ammonia. When recently precipitated, it is a white bulky jelly, but shrinks in drying into a yellowish, translucent, gummy mass, having a conchoïdal fracture. The dry hydrate has, according to Berzelius, the composition, $Zr^{iv}H^2O^3 = ZrO^2.H^2O$; according to Hermann, the hydrate dried at 17°, is $Zr^{iv}H^4O^4 = ZrO^2.2H^2O$. (That obtained by Berzelius was probably dried at a higher temperature.) When ignited, it leaves pure zirconia. It dissolves in 5,000 pts. of water; the solution reddens turmeric-paper. (Brush.)

Zirconia acts both as a base and as an acid: hence called zirconic acid. The hydrate, when precipitated in the cold and washed with cold water, dissolves easily in acids: if precipitated from hot solution, or washed with hot water, it dissolves only in concentrated acids. The saturated solutions have an astringent sour taste, and redden litmus. [For their behaviour with reagents, see p. 1080.]

Zirconates.—Compounds of zirconia with the stronger bases are obtained by precipitating a zirconium-salt with potash or soda; also by igniting zirconia with an alkaline hydrate. Zirconate of potassium thus obtained, dissolves completely in water.

Sodium-salts.—*a. Disodic Zirconate*, $Na^2ZrO^3 = Na^2O.ZrO^2$, is easily obtained, by igniting zirconia with carbonate of sodium, as a crystalline mass which is gradually decomposed by water, with separation of amorphous zirconia.—*β.* When zirconia is heated to whiteness for a considerable time with excess of sodium-carbonate, 2 at. carbonic anhydride are evolved to 1 at. zirconia, and the salt $Na^4ZrO^4 = 2Na^2O.ZrO^2$ is produced. The fused mass treated with water, leaves small hexagonal laminæ of the following salt.—*γ.* An *acid salt*, $Na^2O.8ZrO^2.12H^2O$, is obtained as just described, or by fusing pulverised zircon with excess of sodic carbonate, and treating the mass with water containing hydrochloric acid. It forms hexagonal tables, sometimes aggregated in groups like those of clinochlore. (Hiortdahl, Ann. Ch. Pharm. cxxxvii. 24, 236; Jahresb. 1865, p. 185.)

Calcium-salt.—Zirconate of calcium is obtained by heating a mixture of silica and zirconia (in the proportions to form zircon) with excess of calcium-chloride to bright redness for five or six hours, and treating the product with hydrochloric acid. The zirconate then separates as a shining crystalline powder, together with flocculent silica and amorphous zirconia. (Hiortdahl.)

Zirconate of Magnesium is obtained by placing a mixture of silica and zirconia, together with excess of magnesium-chloride, in a platinum crucible, the bottom of which is covered with sal-ammoniac, heating the mixture quickly to whiteness, and continuing the heat for an hour. On treating the cooled mass with water containing hydrochloric acid, a crystalline powder is deposited, consisting of distinct octahedrons of periclase and prismatic crystals of magnesium-zirconate. (Hiortdahl.)

ZIRCONIUM, OXYCHLORIDES OF. See ZIRCONIUM, CHLORIDE OF (p. 1080).

ZIRCONIUM, SULPHIDE OF. Formed by heating zirconium with sulphur in a vacuum or in hydrogen-gas, the combination in the latter case being attended with slight incandescence. Dark cinnamon-brown powder, acquiring metallic lustre under the burnisher; not altered by water, dilute acids (even nitric acid), or aqueous alkalis; slowly dissolved by nitromuriatic acid; easily decomposed by hydrofluoric acid, with evolution of sulphydric acid. When fused with potash, it yields zirconia and sulphide of potassium.

Frémy, by igniting zirconia contained in a charcoal boat in a stream of carbonic disulphide vapour, obtained a compound (perhaps an oxysulphide) in steel-grey graphitoïdal scales, which yielded a yellow powder, were insoluble in water and in dilute acids, but were easily decomposed by nitric acid, with separation of sulphur.

ZIRCON-SYENITE. The zirconiferous syenite of South Norway.

ZOÏODIN. A name applied by Bonjean to a violet-coloured substance deposited, according to his observations, from the water which drips from baregin (i. 500), taken out of sulphurous springs.

ZOISITE. This name is sometimes applied to all lime-epidotes containing little or no iron (ii. 490); sometimes restricted to a mineral closely allied to epidote in composition and crystalline form, but differing somewhat in the cleavage. It occurs, according to Brooke and Miller, on the Sau Alp and at Sterzing in the Tyrol, at Fusch in Salzburg, at Baireuth and Conradsreuth near Hof in Bavaria, and in the Ural (Dana, ii. 211). Klaproth's analyses of two specimens from the Sau Alp gave:

SiO^2.	Al^2O^3.	Fe^2O^3.	CaO.	MnO.		
45	29	3	21	. .	=	98
44	32	2·5	20	trace	=	98·5

ZOMIDIN (from ζωμός, broth; diminutive ζωμίδιον).—A name applied by Berzelius to the portion of the aqueous extract of meat which is insoluble in alcohol, the soluble portion (about $\frac{4}{5}$ of the whole), being called *osmazome.*

ZOOCHEMICAL ANALYSIS. See ANALYSIS, ORGANIC (i. 250).

ZOOMELANIN. A name applied by Bogdanow (Compt. rend. xlvi. 780), to the black pigment of birds' feathers, probably identical with the melanin of the choroïd coating of the eye. The substance is slightly soluble in water, more soluble in potash and ammonia.

ZOONIC ACID. Berthollet's name for the impure acetic acid obtained by the dry distillation of animal substance.

ZOOSTEARIC ACID. Landerer's name for a fatty acid obtained from the bones of fossil mammalia, and crystallising from alcohol in laminæ. (Buchn. Repert. lxi. 90.)

ZOOTIC ACID. Syn. with HYDROCYANIC ACID (ii. 214).

ZOOTINE-SALT. Nitrate of sodium (iv. 105).

ZOOXANTHIN. The colouring-matter of the red feathers of *Calurus auriceps.* It may be completely extracted by repeated treatment with hot alcohol; and, on evaporating the solution at 60°—70°, there remains a dark-red powder, which, when thoroughly washed with water, leaves the zooxanthin, easily alterable by light. A similar pigment is said to be contained in the light-red fibres of *Calinga cœrulea.* (Bogdanow, Compt. rend. xlv. 688.)

ZORGITE. Native selenide of lead (clausthalite), containing copper or cobalt. (See LEAD, SELENIDES OF, iii. 557.)

ZOSTERA MARINA. This seaweed, which grows abundantly on nearly all seacoasts, leaves 23·3 per cent. ash, containing in 100 pts.: 3·9 pts. K^2SO^4, 4·4 KCl, 0·86 KI, 21·2 NaCl, 21·2 CaO, 5·6 $CaCO^3$, 2·1 $CaSO^4$, 9·8 $Ca^3P^2O^8$, 1·6 MgO, 25·1 SiO^2, 0·7 Al^2O^3, 1·9 Fe^2O^3, with traces of metallic bromide. (Baudrimont, J. Pharm. [3] xlii. 388.)

ZUMIC, or **ZYMIC ACID.** Names formerly applied to the acid (Braconnot's *nanceic acid*), produced in the fermentation of amylaceous substances: since known to consist of impure lactic acid.

ZURLERITE, or **ZURLITE.** Syn. with MELLILITE (iii. 869).

ZWIESELITE. Ferroso-manganous phosphato-fluoride, found in crystalline masses at Zwiesel, near Bodenmais in Bavaria. (See PHOSPHATES, iv. 571.)

ZYGADITE. A silicate of aluminium and lithium, occurring in the Katharina Neufang mine, at Andreasberg in the Harz. It forms twin-crystals, having the appearance of stilbite, slightly translucent, with reddish to yellowish-white colour, and vitreous lustre, inclining to nacreous on the cleavage-faces. Hardness = 6·3. Specific gravity = 2·511—2·512. (Breithaupt, Pogg. Ann. lxix. 441.)

ZYMIC ACID. Syn. with ZUMIC ACID.

ZYMIC INFUSORIA. *Zymiques*, or *Anaërobies*.—Names applied by Pasteur to the infusoria which act as ferments only when the air is excluded,—those which require the presence of air to induce their action being distinguished as *Azymiques* or *Aërobies*.

ZYMOME (from ζύμη, yeast, or ferment).—An old name for the portion of gluten which is insoluble in alcohol.

ZYMOSCOPE. An instrument contrived by Zenneck (Buchn. Repert. lix. 204), for testing the fermenting power of yeast, by bringing it in contact with sugar-water, and observing the quantity of carbonic anhydride evolved.

ZYMURGY. A name applied to that department of technological chemistry which treats of the scientific principles of wine-making, brewing, distilling, and the preparation of yeast and vinegar,—processes in which fermentation plays the principal part.

ADDITIONS AND CORRECTIONS.

ACETANILIDE. *Phenylacetamide*, $C^8H^9NO = NH(C^6H^5)(C^2H^3O)$, is easily produced by cohobating aniline with strong acetic acid, or by boiling the two together, and finally distilling till the product solidifies in the neck of the retort (C. Gr. Williams, Chem. Soc. J. xvii. 106). According to Perkin's observation, crude aniline, prepared by Béchamp's process with an excess of strong acetic acid, sometimes contains acetanilide. According to Lauth (Bull. Soc. Chim. 1866, i. 164), acetanilide is produced, together with phenol, by boiling equal parts of aniline and phenylic acetate in a flask with vertical condensing-tube, or by heating them in a closed vessel to 250°:

$$C^2H^3O.C^6H^5.O + NH^2(C^6H^5) = C^6H^5.H.O + NH(C^6H^5)(C^2H^3O).$$

The phenol and acetanilide are easily separated by distillation, or by treatment with an alkali.

Acetanilide has a specific gravity of 1·099 at 105°, melts at 101°, and distils at 295° under a pressure of 755 mm. Vapour-density, obs. = 4·847; calc. = 4·671. Acetanilide dissolves easily in alcohol, ether, benzene, and volatile oils, and crystallises from the latter in large needles. The alcoholic solution is not precipitated by water. It dissolves easily in warm sulphuric and hydrochloric acids, and is converted, by cold nitric acid, into β-nitraniline. When heated with sodium, it is resolved into aniline, and a small quantity of basic oil having a high boiling-point. (Williams.)

AGE, or AXIN. A fat obtained in Mexico by boiling a species of coccus (*Coccus Axin*) with water. It smells like arnica-flowers, has a dark-brown colour, and buttery consistence; hardens on exposure to the air, and dries up on the skin to an adhesive elastic membrane, like collodion: hence it is used by the Mexicans as an external application, and frequently as a varnish. It is insoluble in water, dissolves with difficulty in cold, more readily in hot alcohol, easily in ether, provided it has not been hardened and oxidised by exposure to the air. Melts at 31°; gives off acrolein by dry distillation. The saponified fat yields a crystallisable acid, melting at 42°, and having the composition of lauric acid, $C^{12}H^{24}O^2$; together with a brown oily acid, called axinic acid, which solidifies somewhat above 0°, dries up very easily, and probably contains $C^{18}H^{28}O^2$. This acid is converted, by oxidation, partly into hypogæic acid, $C^{16}H^{30}O^2$ (soluble in alcohol and ether, and melting at 35°); partly into aginin, an amorphous, light-yellow, brittle substance, insoluble in water, alcohol, and ether, and containing 58·3 to 60·3 per cent. carbon, and 6·7 to 7·5 per cent. hydrogen; it turns brown at 80°, giving off water and colourless gases absorbable by potash. (Hoppe, J. pr. Chem. xxx. 102; Gm. xvii. 46.)

AGININ. See the previous article.

ALCOGEL. }
ALCOSOL. } See COLLOÏDAL ACIDS (p. 1088).

ALOÏN. This substance, the purgative principle of aloes, was discovered by T. and H. Smith (Chem. Gaz. 1851, p. 107; Gm. xvi. 461).

ARIBINE. $C^{23}H^{20}N^4$. (Rieth and Wöhler, Ann. Ch. Pharm. cxx. 247; Jahresb. 1861, p. 532; Gm. xvii. 561.)—A base extracted from the bark of *Arariba rubra*, a Brazilian tree, by exhaustion with water containing sulphuric acid. It may be freed from colouring-matter and other impurities, by treatment with acetate of lead and solution in ether, and separates from the ethereal solution partly in anhydrous rhombic pyramids, partly in hydrated four-sided prisms with oblique end-faces; the latter contain $C^{23}H^{20}N^4.8H^2O$, and give off their water at 100°. Aribine dissolves in 7,762 pts. of water at 23°, more freely in hot water, easily in alcohol, less easily in ether. Its salts are mostly crystallisable, and contain 2 or 4 atoms of acid to 1 atom of base.

—The *hydrochlorate*, $C^{23}H^{20}N^4.2HCl$, crystallises in slender needles, soluble in amylic alcohol, insoluble in ether; from its dilute aqueous solution, caustic soda, sodium-carbonate, ammonia, and lime-water throw down crystalline aribine.—The *chloroplatinate*, $C^{23}H^{20}N^4.2HCl.PtCl^4$, is precipitated in pale-yellow needles.—The *neutral sulphate*, $C^{21}H^{20}N^4.H^2SO^4$, is obtained by decomposing the hydrochlorate with sulphate of silver.—The *acid sulphate*, $C^{23}H^{20}N^4.2H^2SO^4$, is formed by treating aribine with excess of sulphuric acid.

Aribine, heated with iodide of ethyl, forms yellow crystals, probably consisting of iodide of diethyl-aribine, $C^{23}H^{18}(C^2H^5)^2N^4I^2$, which, when decomposed with moist silver-oxide, yields the corresponding hydrate as an amorphous coloured varnish.

ATOMICITY. See CLASSIFICATION (i. 1008—1017).

AXIN. Syn. with AGE (p. 1087).

AXINIC ACID. See AGE (p. 1087).

BENZHYDROL. $C^{13}H^{12}O = C^{13}H^{11}.H.O$.—A monatomic alcohol, produced by the action of nascent hydrogen on benzophenone or phenyl-benzoyl, $C^{13}H^{10}O$, and described in connection with the latter (iv. 478).

BERBERINE. $C^{20}H^{17}NO^4$.—This formula has been established by Perrins (Chem. Soc. Qu. J. xv. 339), by the analysis of the alkaloïd and several of its salts. Berberine is very widely diffused in the vegetable kingdom. Besides the sources of it mentioned in vol. i. (p. 579), it has been found by Perrins in *Hydrastis canadensis* and *Xanthorrhiza apiifolia*, two North American ranunculaceous plants; in a yellow dye-wood from Upper Assam, called *woodunpar*, probably belonging to the menispermaceous order; in a woody root, called *Raiz de São Joao*, or St. John's-root, from Rio Grande; in the yellow bark of the Pachnelo tree, from Bogota; and in the root of *Coptis Tecta* or *Mahmira*, a ranunculaceous plant of Hindostan and China, highly prized for its tonic properties, and known in the bazaars of India as *Mishmee-bitter*. Lastly, the substance called *xanthopicrite*, discovered in 1826 by Chevallier and Pelletan in the bark of *Xanthoxylon Clava Herculis*, has been shown by Perrins to be identical with berberine.

When a dilute solution of iodine in iodide of potassium is added to the solution of any berberine-salt in hot spirit, carefully avoiding an excess of iodine, a crystalline iodine-compound is deposited, in green spangles resembling sulphate of iodoquinine (v. 25), and, like that substance, possessing the power of polarising light. (Perrins.)

BRAZIL-WOOD. (i. 656.)—Preisser's statements respecting the red colouring-matter of this wood are not to be depended upon.

CAMPHRETIC ACID. $C^{10}H^{14}O^7 = \left.\begin{matrix}(C^{10}H^{11}O^4)'''\\ H^3\end{matrix}\right\}O^3$.—A tribasic acid produced by the action of nitric acid upon camphor;—described under PYROCAMPHRETIC ACID (iv. 757).

CESPITINE. $C^8H^{13}N$.—This name is given by Church and Owen (Phil. Mag. [4], xx. 110; Jahresb. 1860, p. 358) to an organic base, found in small quantity, together with pyridine, picoline, collidine, and lutidine, in the liquid obtained by distilling Irish peat at the lowest possible temperature. When purified by fractional distillation, treatment with potash, &c., it forms a colourless oil, miscible in all proportions with water, and agreeing in composition and boiling-point (95°) with amylamine.

CHIMOPHYLLIN. A yellow crystalline body obtained from *Pyrola* (or *Chemophila*) *umbellata* (iv. 760).

CHRYSINIC ACID. A yellow colouring-matter contained in the buds of *Populus nigra* and *P. pyramidalis* (iv. 688).

COLLOÏDAL ACIDS. (Graham, Chem. Soc. J. xvii. 218.)—Colloïdal substances can exist in two states—the liquid state, in which they are soluble in water in all proportions; and the gelatinous or pectous state, in which they are but sparingly soluble. The soluble hydrate of a colloïd substance is called a hydrosol, the gelatinous hydrate a hydrogel. The solubility of a hydrogel diminishes with the quantity of water contained in it. Gelatinous silicic acid containing 1 per cent. of anhydrous silica, dissolves in 5,000 pts. of water; a jelly containing 5 per cent. silica, dissolves in 10,000 pts of water; and anhydrous silica itself is nearly insoluble. The passage from the liquid to the gelatinous state is indicated by a gradual thickening of the solution, which assumes an oily consistence just before gelatinising. In a solution of silicic acid obtained by dialysis (p. 141), the tendency to pass into the gelatinous state increases with the temperature and the concentration of the liquid. A solution containing from 10 to 12 per cent. silica gelatinises in a few hours; a solution containing only 5 per cent. may be kept unaltered for several days; one containing 2 per cent. for many months; another containing 1 per cent. silica remains unaltered for years; and solutions containing only 0·1 per cent. are doubtless quite permanent.

The coagulation of the hydrosol of silicic acid is promoted by small quantities of salts, and, on the other hand, the hydrogel is reconverted into the hydrosol by very small quantities of alkali. One part of sodium-hydrate dissolved in 10,000 pts. of water, gradually liquefies, at 100°, a quantity of gelatinous silicic acid corresponding to 200 pts. of dry silica, and may be separated from the resulting silicious solution by prolonged dialysis in a vacuum.

Silica may be separated both from the hydrosol and the hydrogel by a number of substances, both colloïd and crystalloïd (sulphuric, hydrochloric, nitric, and acetic acids, alcohol, glycerin, sugar-syrup, and other bodies which do not induce gelatinisation), these substances then taking the place of the silica.

The liquid compound of silicic acid with alcohol is called the alcosol, and the gelatinous compound the alcogel of silicic acid. The former produces a nearly colourless solution, which is not gelatinised by salts or by insoluble substances, or even by heating to the boiling-point, but easily gelatinises when concentrated by slow evaporation. Although the alcohol in this compound is less strongly combined than the water in the hydrosol, part of it nevertheless remains behind on distillation, and is ultimately carbonised.

The alcogel of silicic acid is easily prepared by placing masses of gelatinous silica (containing 8 to 10 per cent. SiO^2) in absolute alcohol, and changing the latter repeatedly till the water of the hydrogel is completely replaced by alcohol. An alcogel thus prepared from a hydrogel containing 9·35 per cent., yielded by analysis 88·13 per cent. alcohol, 0·23 water, and 11·64 SiO^2. When immersed in water, the alcogel is gradually reconverted into the hydrogel. By treating the alcogel with ether, benzene, carbonic disulphide, and generally with liquids which mix with alcohol, compounds of silicic acid with these several substances may be obtained; from the ether-compound, in like manner, compounds with fixed oils may be produced.

A glycerogel of silicic acid is obtained by heating the hydrogel with glycerin. It is a perfectly colourless jelly, and so transparent that it cannot be perceived in the liquid. Part of the silica is, at the same time, converted into a liquid compound, the glycerosol of silicic acid. The glycerogel (prepared from a hydrate containing 9·35 per cent. silica) was found to contain 87·44 per cent. glycerin, 3·78 water, and 8·95 SiO^2.

When the hydrogel of silicic acid is immersed, first in moderately dilute sulphuric acid, then successively in stronger acids, and finally in the most concentrated acid (hydric sulphate, H^2SO^4), a gelatinous sulphuric acid compound is obtained, the sulphagel of silicic acid. It is colourless, transparent, of somewhat smaller bulk than the hydrogel, from which it has been prepared; is not altered by heating to the boiling-point of sulphuric acid, but gives up part of its sulphuric acid at a higher temperature. By dialysation with water, it is reconverted into hydrogel; by alcohol into alcogel. Similar compounds may be formed with hydric nitrate, acetate, and formate.

Liquid stannic acid is obtained by dialysing stannic chloride mixed with caustic alkali, or sodic stannate mixed with hydrochloric acid. In both cases a jelly is first formed, which, as the salts are gradually removed, is reconverted into the soluble modification by the small quantity of free alkali present: the latter is removed by prolonged diffusion, most readily after addition of a few drops of iodine-solution. Liquid stannic acid is converted by heat into liquid metastannic acid. Both solutions are easily gelatinised by small quantities of hydrochloric acid or of salts; and, on the other hand, gelatinous stannic acid is reconverted into the liquid acid by free alkali, even at ordinary temperatures.

A solution of gelatinous titanic acid in hydrochloric acid, prepared in the cold, and containing only 1 per cent. SiO^2, yields, in like manner, liquid titanic acid. By heating liquid stannic and titanic acids with alcohol and other liquids, compounds are formed analogous to those obtained in like manner with silicic acid.

Liquid tungstic (or rather metatungstic) acid has been already described (p. 911). A mixture of liquid tungstic and silicic acids does not gelatinise, probably in consequence of the formation of silico-tungstic acids (p. 915).

Liquid molybdic acid is obtained, by dialysing a solution of crystallised sodic molybdate supersaturated with hydrochloric acid, for several days, as a yellow liquid having an astringent taste and acid reaction. It is very permanent, and when left to evaporate, yields soluble molybdic acid as a deliquescent gummy mass, which, when heated, behaves like soluble tungstic acid. Soluble tungstic and molybdic acids yield crystallisable salts by digestion with soda.

CONARITE. A green crystalline mineral, resembling vivianite in structure, found at Röttis, near Jacketa, in the Saxon Voigtland. Specific gravity = 2·46. It appears to be a hydrated nickel-phosphate. (Breithaupt, Jahresb. 1859, p. 806.)

CORIAMYRTIN. $C^{30}H^{36}O^{10}$. (Riban, Bull. Soc. Chim. 1864, i. 87; 1867, i. 79; Laboratory, i. 324.)—The active principle of *Coriaria myrtifolia*, a purgative and very poisonous plant growing in the South of France, in Spain, and in Italy—formerly used for the production of a black dye, and for adulterating senna. Coriamyrtin may be extracted from the berries or the leaves, but the young shoots gathered in March yield the largest product. They are crushed in a mill, and pressed; the juice is treated with basic acetate of lead; and the filtered liquid is freed from excess of lead by sulphydric acid, then evaporated to a syrup, and repeatedly shaken up with ether, which dissolves the coriamyrtin, and leaves it on evaporation in slightly brown crystals, which may be rendered perfectly white and pure by one or two crystallisations from boiling alcohol.

Coriamyrtin is a white, bitter, very poisonous substance, crystallising in oblique rhomboïdal prisms of 98° 40′, having the basal edges truncated. It is anhydrous, and melts at 220° to a colourless liquid, which solidifies to a crystalline mass on cooling. It is slightly soluble in water, easily soluble in boiling alcohol and ether. The alcoholic solution turns the plane of polarisation to the right: $[\alpha] = 24{\cdot}5$ at 20°.

Coriamyrtin is decomposed by fuming hydriodic acid, slowly in the cold, rapidly at 100°, a large quantity of iodine being separated, and a black soft substance deposited; and if the supernatant liquid be decanted, the black substance washed with cold water and dissolved in absolute alcohol, and the resulting solution mixed with a few drops of strong caustic *soda*, a fine purple-red colour is produced, resembling that of an alcoholic solution of fuchsine. This reaction is extremely delicate.

Bromocoriamyrtin, $C^{30}H^{34}Br^2O^{10}$, is formed by adding bromine, drop by drop, to coriamyrtin suspended in cold alcohol. It crystallises from boiling alcohol, in fine anhydrous needles, slightly soluble in cold water, very soluble in boiling alcohol, and having an extremely bitter taste.

Chlorine passed through a mixture of coriamyrtin and water, forms a crystalline substance, composed of several amorphous chlorinated compounds, which cannot be separated by successive crystallisation.

Action of Bases on Coriamyrtin.—Most bases attack coriamyrtin in presence of water. With potash and soda only brown compounds are obtained; but with less active bases, such as baryta and lime, coriamyrtin assumes the elements of five molecules of water, producing a dibasic acid, which unites with the base. Thus, when boiled with excess of baryta, it forms the compound, $C^{30}H^{46}Ba''O^{16} = C^{30}H^{36}O^{10}.BaO.5H^2O$; and with lime-water, in like manner, the salt $C^{30}H^{46}Ca''O^{16}$. These salts do not possess the bitter taste of coriamyrtin.

The acid, separated from them by sulphuric or oxalic acid, remains on evaporation as an amorphous mass. Its aqueous solution decomposes the carbonates of barium and calcium, with effervescence, reproducing the salts just described.

Action of Acids.—Coriamyrtin is dissolved and blackened by strong *sulphuric acid.*—With *fuming nitric acid*, it forms an amorphous nitro-compound, which detonates when heated. It is not attacked by dry *hydrochloric acid gas*, even at 100°, but decomposes when heated to 200° with the aqueous acid containing 2 or 3 per cent. of that gas.

Acetic anhydride and coriamyrtin, heated together to 140° in a sealed tube for about an hour, unite directly without elimination of water. The soft mass thus produced, if thrown into water to free it from acetic acid, ultimately falls to a powder, which may be washed with cold water, then dissolved in alcohol, separated by evaporation, and dried at 100° in a vacuum. It is transparent, nearly colourless, brittle, very bitter, melts below 100°, is insoluble in water, but soluble in alcohol. It has the composition $C^{42}H^{54}O^{19}$, which is that of hexacetic coriamyrtin combined with 3 at. water. Its formation is represented by the equation:

$$C^{30}H^{36}O^{10} + 3(C^2H^3O)^2O = C^{30}H^{30}(C^2H^3O)^6O^{10} + 3H^2O.$$

Glacial acetic acid forms a similar compound with coriamyrtin.

DECYL, RUTYL, CAPRYL. $C^{10}H^{21}$.—The tenth of the series of alcohol-radicles, C^nH^{2n+1}. It has not been isolated.

Hydride of Decyl, $C^{10}H^{22}$ (isomeric with free amyl), is contained in considerable quantity in the portion of American petroleum boiling between 158° and 163° (Pelouze and Cahours, Ann. Ch. Phys. [4], i. 5; Jahresb. 1863, pp. 526, 529).—It is produced also by carefully mixing diamylene, $C^{10}H^{20}$, with bromine, keeping the mixture cool, washing the product with dilute potash, and drying it, then heating it under diminished pressure, and submitting it to fractional distillation (Wurtz, Bull. Soc. Chim. 1863, p. 300; Jahresb. 1863, p. 510). This hydrocarbon resembles amyl in many of its properties (Wurtz). It has an odour of lemons. Specific gravity = 0·757 at 16° (Pelouze and Cahours); 0·753 at 0° (Wurtz). Boiling-point

158°—162° (Pelouze and Cahours); 155°—157° (Wurtz). Vapour-density, obs. = 5·040 (Pelouze and Cahours); 5·05 (Wurtz); calc. = 4·91.

Chloride of Decyl, $C^{10}H^{21}Cl$, obtained from the hydride by the action of chlorine, is a liquid of a light amber colour, boiling at 200°—204° (Pelouze and Cahours); 190°—200° (Wurtz). With alcoholic potash, it yields, amongst other products, a hydrocarbon, which boils between 158° and 160°, and forms a heavy oil with bromine. (Pelouze and Cahours.)

ERUCADIC ACID. $C^{22}H^{42}O^2$.—An acid isomeric with erucic acid (ii. 501), and bearing the same relation to it that elaïdic acid bears to oleic acid. It is produced by the action of nitrous acid gas on erucic acid, and when recrystallised from alcohol, forms a white, inodorous, and tasteless mass, melting at 59° to 60°, and solidifying at 58° to 59° to a shining mass of fine needles. It becomes coloured and odorous at 120°. Its sodium-salt, prepared like that of erucic acid, becomes coloured at 110°. (Websky, J. pr. Chem. lviii. 459.)

ESERINE. Syn. with PHYSOSTIGMINE (iv. 635).

EUGETIC ACID. See Addenda to vol. ii. p. 968.

GLYCEROGEL.
GLYCEROSOL. See COLLOÏDAL ACIDS (p. 1089).

GURJUN-BALSAM. Syn. with WOOD-OIL (v. 1045).

GURJUNIC ACID. The resin left on distilling off the volatile oil of gurjun-balsam.

HYDROGEL.
HYDROSOL. See COLLOÏDAL ACIDS (p. 1088).

HYGROMETRY. (iii. 232).—The formula for calculating the weight of a cubic foot of air, saturated with aqueous vapour, should be:

$$\text{(Weight of cubic foot of dry air)} \,.\, \frac{p-E_t}{p} + \text{Weight of cubic foot of vapour.}$$

When the air is not saturated, if E_d be the elastic force of the vapour at the dew-point, and E_d the elastic force of the vapour at the temperature of the air, then:

$$\text{(Weight of cub. ft. of dry air at } t^\circ) \,.\, \frac{p-E_d}{p} + \text{(Weight of cub. ft. of vapour at } t^\circ) \,.\, \frac{E_d}{E_t}$$

= Weight of cubic feet of moist air not saturated.

This latter formula may be deduced from the formula given on p. 232, vol. iii., for the weight of a cubic foot of non-saturated air, by substituting therein the value of the weight of air saturated with aqueous vapour, determined according to the corrected formula above given.*

ISODULCITE. $C^6H^{14}O^6 = C^6H^{12}O^5.H^2O$.—This saccharine substance, produced by the decomposition of quercitrin (p. 7) under the influence of acids, is isomeric with mannite and dulcite. It crystallises very easily, in large, transparent, regularly-developed crystals, resembling those of cane-sugar: they are hard, grate between the teeth, taste sweeter than grape-sugar, dissolve in 2·09 pts. water at 18°, and easily in absolute alcohol. The solution is dextrorotatory. Isodulcite is not fermentable. It melts, with loss of water, between 105° and 110°, is coloured yellow to brown by strong sulphuric acid, and by alkalis, and reduces cupric oxide. 1,000 c.c. of a copper-solution, equivalent to 5 grms. grape-sugar, are reduced by 5·288 grms. isodulcite.

Isodulcite, heated with hydriodic acid (or with iodine and phosphorus), is converted into a black mass, and yields a small quantity of an oily volatile iodine-compound. By oxidation with nitric acid, it yields an acid resembling saccharic acid, with traces of oxalic acid.

Nitro-isodulcite, $C^6H^9(NO^2)^3O^5$, separates from a solution of isodulcite in a mixture of nitric and sulphuric acids, as a white uncrystallisable body, insoluble in water, but very soluble in alcohol; it explodes slightly by heat, and by percussion. (Hlasiwetz and Pfaundles, Ann. Ch. Pharm. cxxvii. 362.)

LASERPITIN. $C^{24}H^{36}O^7$. (Feldmann, Ann. Ch. Pharm. cxxxv. 336; Bull. Soc. Chim. 1866, i. 457.)—A bitter principle contained in the root of *Laserpitium latifolium*, and exhibiting considerable analogy to those which are extracted from *Athamanta*, *Peucedanum*, *Imperatoria*, and other plants of the composite order. It is extracted by macerating the root with strong alcohol, and when purified from an adhering resin by means of acetate of lead, crystallises in colourless rhombohedral prisms. It is tasteless and inodorous when pure; insoluble in water even at the boiling heat; soluble in benzene, oil of turpentine, and especially in chloroform; soluble also in ether and in carbonic disulphide. It melts at 114°, and solidifies on cooling to a resinous mass, which gradually becomes crystalline. When heated in a tube, it sublimes in oily drops. The alcoholic solution is precipitated by water.

---

* For these corrections I am indebted to the kindness of Mr. P. W. Latham, of Cambridge.—H. W.

Laserpitin is insoluble in dilute acids and alkalis. Strong nitric and sulphuric acids dissolve it, but the solutions are precipitated by water. The alcoholic solution is not precipitated by an alcoholic solution of mercuric chloride, lead-acetate, silver-nitrate, or potassium-iodide. Heated in sealed tubes to 150° with strong hydrochloric acid, or to 200° with dilute sulphuric acid, it yields a black pitchy mass.

By the action of concentrated alcoholic potash, laserpitin is resolved into angelic acid and laserol, $C^{14}H^{22}O^4$, a crystalline resin precipitable by sulphuric acid:

$$\underset{\text{Laserpitin.}}{C^{24}H^{36}O^7} + H^2O = \underset{\text{Laserol.}}{C^{14}H^{22}O^4} + \underset{\text{Angelic acid.}}{2C^5H^8O^2},$$

the decomposition being analogous to that of athamantin (i. 430) into oreoselin and valeric acid:

$$\underset{\text{Athamantin.}}{C^{24}H^{30}O^7} + H^2O = \underset{\text{Oreoselin.}}{C^{14}H^{12}O^4} + \underset{\text{Valeric acid.}}{2C^5H^{10}O^2}.$$

The root of *Laserpitium latifolium* yields, by distillation with water, a small quantity of a volatile oil, similar in taste and odour to oil of pelargonium. This oil does not yield angelic acid by oxidation.

LITHOFELLIC ACID. $C^{20}H^{36}O^4$. (Göbel, Ann. Ch. Pharm. xxxix. 237.—Ettling, *ibid.* xxxix. 242.—Wöhler, *ibid.* xli. 150.—Heumann, *ibid.* xli. 303.—Malaguti and Sarzeau, Compt. rend. xv. 518.—Gm. xvii. 375.)—A crystalline acid, which forms the chief constituent of some kinds of oriental bezoars (i. 584). To extract it, the bezoars are dissolved in boiling alcohol, and the crystals, which form slowly on cooling the solution and concentrating the mother-liquor, are purified by recrystallisation, with the help of animal charcoal. Or, the bezoars, after being exhausted with water, are treated for 24 hours with cold dilute ammonia; the filtrate is decolorised with animal charcoal; and the lithofellic acid is precipitated by dilute sulphuric acid and washed. The acid precipitated from alkaline solutions requires still to be purified by crystallisation from boiling alcohol.

Lithofellic acid crystallises in very small, clear, rhombic prisms, with oblique end-faces; hard and easily pulverisable. Melts at 204° (Göbel), 205° (Wöhler), and solidifies, when not heated above its melting-point, to an opaque crystalline mass. When heated a few degrees above its melting-point, it solidifies to a clear amorphous glass, which becomes electric when rubbed, and melts at 105° to 110° to a viscid mass. Alcohol poured upon this amorphous acid produces a large number of fine cracks, and the acid, when left in contact with a little alcohol, again becomes crystalline (Wöhler). The acid slowly excites a bitter taste in the mouth (Winckler). It dissolves in 29 pts. of alcohol at 20°, and in 6½ pts. of boiling alcohol; the solution has an acid reaction. The acid dissolves in 444 pts. of ether at 20°, and in 47 pts. of boiling ether.

Lithofellic acid, when melted in contact with the air, volatilises in white vapours, which exhale an aromatic odour. By dry distillation it loses 1 at. water, and is converted into an acid oil, $C^{20}H^{34}O^3$, called pyrolithofellic acid. Lithofellic acid dissolves in strong sulphuric acid, forming a solution which becomes milky on addition of water. Hot nitric acid converts it into a yellow acid, soluble in acetic acid, crystallising therefrom, and containing $C^{20}H^{28}(NO^2)^2O^8$. (Malaguti and Sarzeau.)

Lithofellic acid, heated with sugar and sulphuric acid, produces a violet coloration similar to that which is produced in like manner by the biliary acids.

The lithofellates are but little known. The acid dissolves easily in caustic alkalis and alkaline carbonates.—The *ammonium-salt* is known only in solution.—The *potassium-* and *ammonium-salts* are amorphous and gummy.—The *barium-salt* forms crystals very soluble in alcohol.—A *lead-salt*, of variable composition, is obtained as a white precipitate, slightly soluble in water, somewhat more soluble in alcohol, on mixing an alcoholic solution of the acid containing a little ammonia, with neutral acetate of lead.—The *silver-salt*, obtained in like manner by precipitation, appears to contain $C^{20}H^{35}AgO^4$.

MACLURIN. Syn. with MORINTANNIC ACID (iii. 1049).

METAPURPURATES. See PURPURATES (iv. 748).

MUCONIC ACID. $C^6H^6O^4$. (F. Bode, Ann. Ch. Pharm. cxxxii. 95; Jahresb. 1864, p. 400.)—A dibasic acid produced by the action of sodium-amalgam on the chlorinated acid, $C^6H^4Cl^2O^4$, obtained by treating mucic acid with pentachloride of phosphorus (iii. 1058). On treating the resulting mass with hydrochloric acid, evaporating to dryness, and exhausting with ether, a solution is obtained, which yields muconic acid as a white laminar mass, melting at 195°, solidifying at 185°, easily soluble in alcohol, sparingly in ether, soluble in 110 pts. of water at 16°, and crystallising from hot water in long prisms, often grouped in stars.

The muconates are for the most part easily soluble and amorphous; the ammonium-salt (but not the free acid) gives a reddish precipitate with ferric chloride, and, if not too dilute, a white precipitate with silver-nitrate.—The *neutral zinc-salt*, $C^6H^4Zn''O^4$, separates from hot water as a white amorphous mass. The *ethylic ether* is a colourless liquid which sinks in water.

NAPHTHYL-COMPOUNDS. *Nitrate of Diazonaphthalene*, $C^{10}H^6N^2.NHO^3$, is formed by the action of nitrous acid on moistened nitrate of naphthylamine, and is obtained, by spontaneous evaporation of the aqueous solution filtered from a brown-red amorphous product, in white, easily soluble, explosive needles.—*Perbromide of Diazonaphthalene*, $C^{10}H^6N^2.HBr^3$, prepared like the corresponding benzene-compound (iv. 431), forms orange-yellow crystals.—The *platinum-salt*, $2(C^{10}H^6N^2.HCl).PtCl^4$, forms short, yellowish, nearly insoluble prisms.—*Diazonaphtholimide*, $C^{10}H^6N^2.HN$, passes over as a yellowish oil when the substance formed by the action of ammonia on the perbromide is distilled with water. It smells like naphthalene, and turns brown in contact with the air.

Naphthyl-hydrate, or *Naphthyl-alcohol*, $C^{10}H^8O = C^{10}H^7.H.O$.—Produced, with evolution of nitrogen, when the aqueous solution of nitrate of diazonaphthalene is boiled:

$$C^{10}H^6N^2 + H^2O = C^{10}H^8O + N^2.$$

When purified by solution in potash, precipitation with acetic acid, and distillation, it forms shining white laminæ, which melt at 91° to a colourless oil. It volatilises without decomposition, burns with a smoky flame; dissolves sparingly in water, easily in alcohol, ether, and benzene; smells like creosote, and has a burning taste. It unites with strong bases, forming easily decomposible compounds; is converted by nitric acid into nitro-compounds, and by bromine into bromonaphthyl-alcohol. (Griess, Chem. Soc. J. xix. 90; Jahresb. 1866, p. 459.)

Naphthylsulphydrate, $C^{10}H^7.H.S$.—Produced by the action of nascent hydrogen (zinc and sulphuric acid) on naphthylsulphurous chloride (p. 561):

$$C^{10}H^7ClSO^2 + 3H^2 = C^{10}H^8S + HCl + 2H^2O.$$

It passes over on distillation as a colourless, strongly refracting oil, having an unpleasant odour, a specific gravity of 1·146 at 23°, boiling without decomposition at 285°, not miscible with water, sparingly soluble in alkalis, easily soluble in alcohol and ether. It acts strongly on finely pulverised mercuric oxide, forming *naphthyl-mercuric sulphide*, $(C^{10}H^7)^2Hg''S^2$, which separates from hot alcohol as a pale-yellow powder.—The corresponding *lead-compound*, $(C^{10}H^7)^2Pb''S^2$, is deposited as a lemon-yellow fusible precipitate, on mixing the alcoholic solutions of lead-acetate and naphthylsulphydrate.—The *copper-compound* is a pale-yellow precipitate.

Naphthyl-disulphide, $(C^{10}H^7)^2S^2$, separates, by spontaneous evaporation from an alcoholic solution of naphthylsulphydrate saturated with ammonia or potash, in yellow monoclinic crystals. It melts at 85°, is insoluble in water, slightly soluble in alcohol, easily in ether. In contact with zinc and sulphuric acid, it is reconverted into naphthylsulphydrate. (Schertel, Ann. Ch. Pharm. cxxxii. 91.)

NITROPOPULIC ACID. Syn. with Dinitrosalicylic acid. (See SALICYLIC ACID, p. 139).

OLEANDRINE. An alkaloïd contained, together with pseudocurarine, in the leaves and branches of the oleander. (See PSEUDOCURARINE, iv. 743.)

PYROLITHOFELLIC ACID. See LITHOFELLIC ACID (p. 1092).

RUTYL. Syn. with DECYL (p. 1090).

SULPHAGEL. See COLLOÏDAL ACIDS (p. 1089).

WEIGHTS AND MEASURES. The weights and measures used in this Dictionary are chiefly those of the French decimal system. The following tables (published by Messrs. De la Rue and Co.) exhibit their equivalents in English weights and measures:—

French Measures of Length.

	In English inches.	In English feet = 12 inches.	In English yards = 3 feet.	In English fathoms = 6 feet.	In English miles = 1760 yards.
Millimetre	0·03937	0·003281	0·0010936	0·0005468	0·0000006
Centimetre	0·39371	0·032809	0·0109363	0·0054682	0·0000062
Decimetre	3·93708	0·328090	0·1093633	0·0546816	0·0000621
Metre	39·37079	3·280899	1·0936331	0·5468165	0·0006214
Decametre	393·70790	32·808992	10·9363306	5·4681653	0·0062138
Hectometre	3937·07900	328·089917	109·3633056	54·6816528	0·0621382
Kilometre	39370·79000	3280·899167	1093·6330556	546·8165278	0·6213824
Myriametre	393707·90000	32808·991667	10936·3305556	5468·1652778	6·2138242

1 Inch = 2·539954 Centimetres.
1 Foot = 3·0479449 Decimetres.

1 Yard = 0·9143835 Metre.
1 Mile = 1·6093149 Kilometre.

French Measures of Surface.

	In English square feet.	In English square yards = 9 square feet.	In English poles = 272·25 square feet.	In English roods = 10890 square feet.	In English acres = 43560 square feet.
Centiare or Square Metre	10·764299	1·196033	0·0395383	0·0009885	0·0002471
Are, or 100 Square Metres	1076·429934	119·603326	3·9538290	0·0988457	0·0247114
Hectare, or 0,000 Square Metres	107642·993419	11960·332602	395·3828959	9·8845724	2·4711431

1 Square Inch = 6·4513669 Square Centimetre.
1 Square Foot = 9·2899683 Square Decimetres.

1 Square Yard = 0·83609715 Square Metre or Centiare.
1 Acre = 0·40467102 Hectare.

French Measures of Capacity.

	In cubic inches.	In cubic feet = 1728 cubic inches.	In pints = 4·65923 cubic inches.	In gallons = 8 pints = 277·27384 cubic inches.	In bushels = 8 gals. = 2218·19075 cubic inches.
Millilitre, or Cubic Centimetre . . .	0·06103	0·000035	0·00176	0·0002201	0·0000275
Centilitre, or 10 Cubic Centimetres . .	0·61027	0·000353	0·01761	0·0022010	0·0002751
Decilitre, or 100 Cubic Centimetres . .	6·10271	0·003532	0·17608	0·0220097	0·0027512
Litre, or Cubic Decimetre . . .	61·02705	0·035317	1·76077	0·2200967	0·0275121
Decalitre, or Centistere	610·27052	0·353166	17·60773	2·2009668	0·2751208
Hectolitre, or Decistere	6102·70515	3·531658	176·07734	22·0096677	2·7512085
Kilolitre, or Stere, or Cubic Metre . .	61027·05152	35·316581	1760·77341	220·0966767	27·5120846
Myrialitre, or Decastere	610270·51519	353·165807	17607·73414	2200·9667675	275·1208459

1 Cubic inch = 16·386176 Cubic Centimetres.
1 Gallon = 4·543458 Litres.

1 Cubic Foot = 28·315312 Cubic Decimetres.

French Measures of Weight.

	In English grains.	In troy ounces = 480 grains.	In avoirdupois lbs. = 7000 grains.	In cwts. = 212 lbs. = 784000 grains.	Tons = 20 cwts. = 15680000 grains.
Milligramme	0·01543	0·000032	0·0000022	0·0000000	0·0000000
Centigramme	0·15432	0·000322	0·0000220	0·0000002	0·0000000
Decigramme	1·54323	0·003215	0·0002205	0·0000020	0·0000001

Sulphocarbonic ethers (*continued*)—
Methyl- and Ethyl-amylic disulphocarbonates 496
Amylic trisulphocarbonate . . 497
Cetyl-disulphocarbonic acid . . —
Ethyl-monosulphocarbonic acid . —
Ethyl-monosulphocarbonic sulphide —
Ethylic monosulphocarbonate. . —
Ethyl-disulphocarbonic or Xanthic acid 498
Ethyl-disulphocarbonic sulphide . 499
Ethylic disulphocarbonate: Xanthic ether 500
Ethyl-trisulphocarbonic acid . . —
Ethylic trisulphocarbonate . . —
Methyl-disulphocarbonic acid . 501
Methylic disulphocarbonate . . —
Sulphocarbonic ethers containing diatomic alcohol-radicles:
Amylenic trisulphocarbonate . . —
Ethylenic trisulphocarbonate . . —
Ethylenic disulphocarbonate, or Xanthate 502
Methylenic, Tritylenic, and Tetrylenic trisulphocarbonates . . —
Sulphocarbovinic acid (s. Ethyl-disulphocarbonic acid, p. 498).
Sulphocetic acid (s. Cetylsulphuric acid, p. 621).
Sulphochlorobenzamide. . . . —
Sulphochlorobenzoic acid . . . —
Disulphochlorobenzoic acid . . 503
Sulphocholeic acid. . . . . —
Sulphocinnamic acid . . . . —
Sulphocumenic acid . . . . —
Sulphocumide. . . . . . —
Sulphocyanacetic acid (s. Thiocyanoglycollic acid).
Sulphocyanic acid. 504
Metallic sulphocyanates. . . 505
Sulphocyanic anhydride . . . 515
Iodocyanic sulphide . . . 516
Sulphocyanic ethers 516
Allylic sulphocyanate, or volatile oil of mustard . . . . . —
Amylic sulphocyanate . . . 519
Ethylic sulphocyanate . . . —
Ethylenic sulphocyanate . . 520
Hexylic sulphocyanate . . . —
Methylic sulphocyanate . . . —
Naphthylic sulphocyanate . . 521
Phenylic sulphocyanate . . . —
Sulphocymenic acid (s. Cymylsulphurous acid, ii. 298).
Sulphodraconic acid . . . . —
Sulphoflavic acid (s. Indigosulphuric acids, iii. 262).
Sulphoform . . . . —
Sulphofulvic acid (s. Indigosulphuric acids, iii. 262).
Sulphoglucic acid (s. Glucososulphuric acid, ii. 872)
Sulphoglutinic acid . . . . —
Sulphoglyceric acid (s. Glycerosulphuric acid, ii. 892).
Sulphoglycollic acid (s. Ethylenic acid, sulphate of, ii. 582).
Suphohippuric acid . . . . —
Sulpho-hydroquinonic acids (s. Hydroquinone, iii. 217).
Sulphomargaric and Sulpholeic acids . 522
Sulpholignic acid . . . . . —
Sulphomannitic acid . . . . —
Sulphomelanurenic acid. . . —

PAGE
Sulphomellonic acid 522
Sulphomethylic acid (s. Methylsulphuric acid, p. 626).
Sulphomolybdates (s. Molybdenum, iii. 1043).
Sulphomorphide . . . . . —
Sulphonaphthalene. . . . . —
Sulphonaphthalic acid (s. Sulphurous ethers, p. 560).
Sulphonaphthalidamic acid (s. Naphthionic acid, iv. 17).
Sulphonaphthanic acid (s. Sulphonaphthalic acid).
Sulphonarcotide 523
Sulphophenic acid (s. Sulphuric ethers, p. 627).
Sulphophenylamide . . . . —
Sulphophenylic chloride (s. Sulphurous ethers, p. 564).
Sulphophenylic hydride (p. 564).
Sulphophenylsuccinamic acid . . 524
Sulphophloramic acid . . . . —
Sulphophloretic acid . . . . —
Sulphophosphates and Sulphophosphites (s. Phosphorus, sulphides of, iv. 603, 604).
Sulphopianic acid (s. Opianic acid, iv. 206).
Sulphopurpuric acid (s. Indigosulphuric acids, iii. 262).
Sulphopyromucic acid . . . . —
Sulphoquinic acid (s. Quinine-sulphuric acid, iv. 26).
Sulphoretinylic acid . . . . —
Sulphorufic acid (s. Indigosulphuric acids, iii. 262).
Sulphosaccharic or Sulphoglucic acid . —
Sulphosalicylic acid 525
Sulphosinapic acid 526
Sulphosinapisin . . . . . —
Sulphosuccinic acid 527
Sulphosulphamylic acid (s. Amylsulphurous acid, p. 552).
Sulphotellurates and Sulphotellurites (s. Tellurium, p. 718).
Sulphothymic acid (s. Cymylsulphurous acid, ii. 298).
Sulphotoluolamide or Sulphobenzylamide . . . . —
Sulphotoluylic acid (s. Sulphurous ethers, p. 553).
Sulphotolylamic acid . . . . —
Sulphotriphosphamide 528
Sulphovanadates and Sulphovanadites (s. Vanadium, Sulphides of).
Sulphovinic acid (s. Ethylsulphuric acid, p. 622).
Sulphoviridic acid (s. Indigosulphuric acids, iii. 262).
Sulphoxalenide and Sulphoxamide (s. Cyanogen, Sulphydrates of, ii. 285). .
Sulphoxybenzoic acid . . . . —
Sulphur . . . . . . —
Sulphur, Bromides of 533
Sulphur, Chlorides of, or Sulphides of chlorine . . . . . . —
Disulphide of Chlorine . . . —
Protosulphide of Chlorine . . 535
Tetrachloride of Sulphur . . —
Sulphur, Cyanide of (s. Sulphocyanic anhydride, p. 515.) . . . .
Sulphur, Detection and Estimation of:
1. Reactions 536
2. Quantitative estimation and separation 537
3. Atomic weight of sulphur . . 539

Vaugnerite	—
Vauqueline	—
Vauquelinite	—
Vegetable alkali	—
Vegetable ethiops	—
Vegetable Ivory	—
Vegetable parchment (s. Cellulose, i. 819).	
Vegetables, Nutrition of (s. Nutrition of Plants, iv. 162).	
Vein-stones	995
Venetian red	—
Venetian Talc (s. Talc, p. 656).	
Venice Turpentine (s. Turpentine, p. 919).	
Verantin	—
Veratric acid	—
Veratrin (s. Veratrum-resin).	
Veratrine	996
Veratrol	997
Veratrum	—
Veratrum-resin	—
Verbascum	—
Verbena-oil	—
Verdigris	—
Verditer	—
Vermiculite	—
Vermillion (s. Mercuric Sulphide, iii. 913).	
Vermontite	998
Vernonia	998
Vertidine	—
Vesuvian	—
Vetch (s. Vicia).	
Vetiver	—
Viburnic acid	—
Viburnum	—
Vicia	999
Vignite	—
Villarsite	—
Vine	—
Vinetin	1000
Vinegar (s. Acetic acid, i. 7).	
Viola	—
Violan	—
Violantin	—
Violenic acid (s. Viola).	
Violet (Aniline)	1001
Violin or Viola-emetin	—
Violine	—
Violuric acid	—
Virginia creeper	1002
Virginic acid	—
Viride æris (s. Verdigris).	
Viridic acid	—
Viridin (s. Chlorophyll, i. 922).	
Viridine	1003
Virola tallow	—
Viscautschin	—
Viscene	—
Viscic acid	—
Viscin	—
Viscinol	—
Viscosimeter	—
Viscum	1004
Vitellin	—
Vitex	—
Vitis (s. Vine and Virginia Creeper).	
Vitrinopal	—
Vitriol	—
Vitriol-ochre	—
Vitrile (s. Vitrinopal).	
Vitrum Antimonii	1005
Vivianite	—
Völcknerite (s. Hydrotalcite, iii. 219).	
Voglite	—
Voigtite	—
Volborthite	—
Volcanic glass (s. Obsidian, iv. 169).	
Volcanite	—
